Morphostratigraphy/Allostratigraphy

P D Hughes, The University of Manchester, Manchester, UK

Morphostratigraphy

Morphostratigraphy can be defined as the subdivision of sedimentary units based on surface form. [Frye and Willman \(1962\)](#) defined a morphostratigraphical unit as 'a body of rock that is identified primarily from the surface form it displays.' However, morphostratigraphical units often incorporate some element of lithological criteria ([Bowen, 1978](#), p. 94). As a result, the spatial distribution of morphostratigraphical units is frequently presented using geomorphological maps, incorporating both morphological and lithological criteria. Morphostratigraphy is widely employed in Quaternary Science to subdivide a range of sedimentary successions and is a key component of geomorphology – the study of Earth surface processes and landforms ([Hughes, 2010](#)). Several examples of its application are outlined in the following sections.

Glacial Sediments

Interpretation of glacial landforms and associated sediments, and the mapping of their relative position in the landscape often provides the basis for stratigraphical subdivision – especially, though not exclusively, in upland settings ([Hughes, 2010](#); [Figures 1 and 2](#)). However, Quaternary deposits are often not morphologically expressed at the surface because of erosion or burial by more recent sediments. In these circumstances, morphostratigraphy alone is limited in its power to subdivide the glacial record, and support is required from lithostratigraphical criteria ([Pitkäranta, 2009](#)). This is highlighted in papers by [Owen et al. \(1998\)](#) and [Hughes et al. \(2005, 2006\)](#) who recognized the importance of a combined morphological and sedimentological approach to subdivide glacial deposits in mountain regions. The linkage of landforms and subsurface sediments and relating them genetically to process landform studies underpins the 'landsystems' approach in glacial geomorphology ([Evans, 2003](#)).

Fluvial Sediments

Terraced fluvial successions represent a classic example where morphostratigraphy has been widely applied (e.g., [Antoine et al., 2000](#); [Sancho et al., 2008](#)). Interpretation of terrace successions on the basis of altitude is commonly the reverse of that in glaciated areas, as the terrace age usually decreases with lower altitude. This is because phases of fluvial aggradation interrupted by phases of incision often lead to a step-like profile in valley-side fluvial sediments and a terraced morphology ([Figure 3](#)). While the relative height of terrace surfaces reflects the relative ages of these surfaces, it conceals the complexities of the internal structure of terrace units. Thus, based on surface form alone, only a simplified history of fluvial activity can be inferred. A more comprehensive understanding of fluvial history can be achieved using a three-dimensional

alluvial stratigraphical approach utilizing spatial variability in surface form and lithological characteristics ([Mackey and Bridge, 1995](#)). Thus, most modern studies of alluvial stratigraphy combine morphological mapping with lithological evidence from sediment cores, test pits, or section exposures (e.g., [Howard et al., 2004](#); [Kasse et al., 2005](#); [Woodward et al., 2008](#); [Figure 3](#)).

Lake-Level Fluctuations

Changes in lake levels through time are often recorded by paleoshorelines, sometimes termed paleostrandlines. Former shorelines record lake-level stability during high stands and provide important information regarding changing moisture conditions during the Quaternary. For example, [Schuster et al. \(2005\)](#) identified paleoshorelines of Holocene Lake Mega-Chad, in Africa, using satellite imagery to identify morphodynamic features of sedimentary systems. Most studies, however, utilize both morphological and lithological criteria identified in the field. [Briggs et al. \(2005\)](#) reconstructed late Pleistocene and late Holocene lake highstands in the Pyramid Lake subbasin of Lake Lahontan, Nevada, USA, on the basis of morphological evidence of paleoshorelines and trenches cut through beach deposits. Similarly, in Mongolia, [Komatsu et al. \(2001\)](#) identified paleoshorelines using both satellite/field-based morphological mapping and near-surface lithology.

However, because shorelines tend to record lake-level stability, rapid fluctuations in lake levels may not be clearly recorded by former lake shorelines. Given the rapid millennial to centennial global climate fluctuations that occurred during the last cold stage, the degree to which these changes are recorded in lake shorelines is questionable. Lake-level histories are therefore better recorded in lithostratigraphical and biostratigraphical evidence from subsurface sediments across a lake basin (cf. [Digerfeldt et al., 2000](#); [Frogley et al., 2001](#)). As with other evidence partly recorded by surface form, while morphostratigraphy is an important component in understanding environmental change in lacustrine settings, surface forms should be integrated with other records.

Sea-Level Change

Changes in sea level are often recorded by landforms such as raised beaches. For example, morphological mapping has been a prerequisite of studying the altitudinal variation of raised shoreline deposits in northwest Europe ([Bates et al., 2000](#); [Cullingford, 1977](#)). However, these and other studies utilized natural field sections and boreholes to understand the morpho- and lithostratigraphy of former shoreline areas. Furthermore, reconstruction of sea-level history on the basis of morphostratigraphy alone fails to fully take into account sea-level transgressions and regressions through time. For example, in the Firth of Forth area of eastern Scotland, only seven

Figure 1 Surface landforms are especially important in subdividing glacial deposits in mountainous regions. In this photograph, four sets of stratigraphically separate suites of moraines (labeled A–D) can be identified in a cirque → valley → piedmont system in the Durmitor massif, Montenegro. Photograph by Philip Hughes, May 2005.

shorelines, including the present, are recorded by surface morphology, while 11 shorelines are recorded by both surface and buried shorelines (Sissons, 1983; Figure 4). Thus, when used alone, morphostratigraphical approaches are limited in their capacity to understand the order of sedimentary changes through time in former coastal settings and should ideally be combined with subsurface lithostratigraphical investigation.

The examples discussed above represent only some of the types of sedimentary successions to which morphostratigraphy can be applied. Morphostratigraphy can be used to subdivide any sedimentary succession where surface landform is an important defining criterion. Some studies also utilize landform morphology to differentiate between erosional surfaces of different ages, such as shore platforms or former cliff lines (e.g., Bates et al., 2000; Dawson et al., 1999), although when strictly defined, morphostratigraphy concerns only the ordering and subdivision of sediments and associated landforms. Thus, while erosional forms may be important toward understanding geomorphological relationships, they cannot be included within morphostratigraphical units because they are not sediment units. However, in the example of shore platforms, associated sediments such as beach deposits can be defined as morphostratigraphical units. This rule should apply to all Quaternary environmental settings and, for example, in glacial environments, neither cirques nor troughs can represent morphostratigraphical units – these can only be defined stratigraphically by the associated sediments that these landforms contain.

Some authors have argued that morphostratigraphical units should have no formal stratigraphical status and that they should not be applied with any formal stratigraphical implication (e.g., Bowen, 1978; Rawson et al., 2002, pp. 11–12; Richmond, 1959). However, by integrating morpho- and lithostratigraphy, there is a strong case for accepting morphostratigraphical units as formal stratigraphical units. In many cases, surface form defines the boundaries between sedimentary units, yet in practice, it is rare that morphostratigraphical units themselves are not defined using at least some

lithological criteria (Bowen, 1978, p. 94). For example, glacial units may be recognized by lithological criteria incorporating a range of sedimentological characteristics such as striated subrounded boulders and diamicton exposures, but separated by morphological criteria, such as moraine position. The fact that morphological and lithological criteria are often used to describe and subdivide glacial sediments led Hughes et al. (2005) to argue for the integration of morphostratigraphy within lithostratigraphy and the development of a formalized morpho-lithostratigraphical approach. In this scheme, morphostratigraphical units can be subdivided using formal lithostratigraphical terms, such as bed, member, formation, and group. Soil development may be an important characteristic of certain deposits and landforms. Pedostratigraphical units are separate and of equal rank to lithostratigraphical units, but both share overlapping textural and compositional attributes, and may be useful as a marker horizon when applied in conjunction with the morphostratigraphy (Figure 5). Hughes et al. (2005) argued that the formalization of morpho-lithostratigraphical approaches was useful for the development of robust terrestrial stratigraphical frameworks and for the systematic comparison of sediment units across wide areas in not just glacial, but in a range of Quaternary sediments. Unfortunately, however, the past status of morphostratigraphy has inhibited the integration of geomorphological data within the formal stratigraphical method.

Allostratigraphy

An allostratigraphical unit is a body of sedimentary rock that is defined and identified by its bounding discontinuities (North American Commission on Stratigraphic Nomenclature, 1983, pp. 865–867). The fundamental units are the same as for lithostratigraphy, but with the prefix allo-, that is, allomember/alloformation. Allostratigraphical units may be defined to distinguish between (a) successions of lithologically similar deposits bounded by discontinuities, (b) contiguous, genetically related heterogeneous deposits bounded by discontinuities, and (c) geographically separated units separated by discontinuities. In the *North American Stratigraphic Code* (NACSN, 1983), the bounding discontinuities are described as unconformities, disconformities, or the present-day land surface, although fault boundaries are excluded (Rawson et al., 2002, pp. 10–11). In some instances, prolonged surface exposure may sometimes be recorded by soil development resulting in allostratigraphical boundaries being marked by soil horizons or paleosols (Autin, 1992).

Allostratigraphical units are essentially the same as unconformity-bounded units and are analogous to syntems as defined in the *International Stratigraphic Guide* (Salvador, 1994, p. 50). Allostratigraphy also represents a form of sequence stratigraphy. However, sequence stratigraphy tends to be applied at a larger scale and, unlike allostratigraphy, does not cover the special case of sediment or rock bodies of similar lithologies separated by discontinuities (Rawson et al., 2002, pp. 10–11). The latter is an important advantage of allostratigraphy because using a lithostratigraphical approach, lithologically similar units separated by discontinuities units would be classified as a single unit. Conversely, allostratigraphy also

Figure 2 A glacial geomorphological map from Mount Smolikas, Greece. Here, the glacial sequence can be subdivided on the basis of moraine position. Glacial units are identified by the letters a–g and correspond to the following subdivision, in order of age (oldest first), Unit 1: a, Unit 2: b, Unit 3: c/d/e, and Unit 4: f/g. Reproduced from Hughes PD, Gibbard PL, and Woodward JC (2005) Quaternary glacial records in mountain regions: A formal stratigraphical approach. *Episodes* 28: 85–92.

provides an objective method for the definition of sediment units that contain genetically related but heterogeneous sedimentary deposits (Figure 6). For example, Miall (1997, p. 12) argued that “allostratigraphic methods enable the erection of a sequence framework that avoids the cumbersome nature of lithostratigraphy, whereby lateral changes in facies within a unit of comparable age require a change in name.” A common goal of allostratigraphy is that, for both homogeneous and heterogeneous sediment units, the defining discontinuities have time-stratigraphical significance and it is in this respect that the approach is similar to morphostratigraphy, which assumes time-stratigraphical significance for surface forms. Consequently, most Quaternary sedimentary successions that can be subdivided primarily on the basis of surface form, that is, using morphostratigraphy, can be subdivided using an allostratigraphical approach.

The application of allostratigraphy is discussed in the following paragraphs with reference to alluvial, lacustrine, glacial, and fluvial deposits – examples used in the original definition in the *North American Stratigraphic Code* (NACSN, 1983). However, the approach is not limited to these settings and can be applied to a range of Quaternary sedimentary successions where discontinuities are important criteria in differentiating between sediment units, including marine shoreline successions (Figure 4).

Lake-Level Fluctuations

Sedimentation in lakes is largely continuous although variable in terms of rate and composition depending on the depth of the water column and environmental conditions within the lake and also at the surface. When erosion occurs, it is often

Figure 3 (a) Schematic diagram showing the Pleistocene and Holocene fluvial record in the Voidomatis River basin in northwest Greece (based on Hamlin, 2000; Lewin et al., 1991). (b) The lithological composition of the gravels in the coarse-grained alluvial units (after Lewin et al., 1991). In: Smith DE and Dawson AG (eds.) *Shorelines and Isostasy*, pp. 210–225. London: Academic Press.

Figure 5 Down-valley cross-section of a hypothetical glaciated cirque-valley system. The diamicton units are glacial in origin and the boulder unit represents a periglacial rock glacier. Sediment landforms are subdivided on the basis of morphostratigraphical position in conjunction with lithological and pedological attributes. Reproduced from Hughes PD, Gibbard PL, and Woodward JC (2005) Quaternary glacial records in mountain regions: A formal stratigraphical approach. *Episodes* 28: 85–92.

Figure 6 An example of allostratigraphical classification in alluvial and lacustrine deposits in tectonic sedimentary basin (graben). Allostratigraphy provides a useful method for the subdivision of sediment units that contain genetically related but heterogeneous sedimentary deposits. Rather than dividing units on the basis of lithology, they are separated on the basis of discontinuities (or disconformities). Reproduced from [North American Commission on Stratigraphic Nomenclature \(1983\)](#) North American stratigraphic code. *American Association of Petroleum Geologists Bulletin* 67: 841–875. AAPG ©1983. Redrawn with permission of the American Association of Petroleum Geologists.

indicative of major changes in the geomorphological state of the lake basin, such as major lake-level regressions, or subsequent debris flows, or landslides. Lateral variation in lithology between gravel and clay deposits will reflect position in the basin and vertical variation in lithology may reflect changes in lake level. In a lithostratigraphical approach, the lacustrine clays and the alluvial gravels would be divided into separate stratigraphical units and the presence of multiple units separated by discontinuities would not be recognized. Furthermore, an allostratigraphical approach enables genetically related heterogeneous deposits to be grouped within a single stratigraphical unit, as the subdivision of sediment units relies on the presence of a discontinuity (Figure 6).

Allostratigraphy has been employed by numerous researchers to understand the stratigraphy of lacustrine deposits, including at Lake Bonneville ([Oviatt et al., 1994](#)) and Lake Canyon ([Pederson, 2000](#)), both in the United States, and also at Lake Rotorua in New Zealand. Here, [Marx et al. \(2009\)](#) used allostratigraphy to subdivide and order lacustrine terraces (paleoshorelines). They argued that “flights of terraces do not yield the stacking relationships useful in erecting a standard lithostratigraphy, but allostratigraphy provides an objective means of grouping heterogeneous lacustrine deposits that are nevertheless genetically related” (p. 352). At Lake Rotorua, bounding discontinuities are represented by pyroclastic deposits such as tephra marker horizons.

Glacial Sediments

Glacial units are usually separated by erosional boundaries, reflecting each subsequent glacier advance. Moreover, glacial units may appear indistinguishable on the basis of lithological criteria alone. They can often be separated on the basis of their lateral extent and on the basis of moraine position. Consequently, glacial deposits appear to have all the characteristics suited to the allostratigraphical approach in that they represent successions of lithologically similar, contiguous, and geographically separated units – all separated by discontinuities. Thus, glacial units have been recognized as allostratigraphical units by workers such as [Borgert et al. \(1999\)](#), [Dahms \(2002\)](#), and [James et al. \(2002\)](#).

Allostratigraphy is sometimes thought especially suitable for glacial successions because sediment units may appear indistinguishable on the basis of lithological criteria alone “due to the complexity and small-scale variation of the lithologic units in these deposits” ([Räsänen et al., 2009](#), p. 4). [Räsänen et al. \(2009\)](#) argued for the combined use of allo- and lithostratigraphy in a similar manner to [Hughes et al. \(2005\)](#) who argued for the integrated use of morpho- and lithostratigraphy. However, the two approaches vary in an important respect: in [Räsänen et al. \(2009, p. 9\)](#) the ‘allounits are given preference, and the lithostratigraphic units are subordinate to the allostratigraphy’; while in [Hughes et al. \(2005\)](#), morphological and lithological units are considered of equal importance. A detailed discussion is provided in [Hughes \(2010\)](#).

Fluvial Sediments

Fluvial successions are another classic case where allostratigraphy can be applied. In many river basins, alternating phases of fluvial deposition and incision produce terraced sedimentary units bounded by discontinuities. As noted earlier, most workers apply both morpho- and lithostratigraphical approaches (e.g., [Kasse et al., 2005](#); [Lewin et al., 1991](#)) and, outside of North America, there are few examples where allostratigraphy has been applied. However, because fluvial successions often represent both contiguous discontinuity-bounded and geographically separated discontinuity-bounded deposits of similar lithology, an allostratigraphical approach can be applied.

In a study of the Amite River (Louisiana, United States), [Autin \(1992\)](#) argued that allostratigraphy provides several benefits for studying floodplain stratigraphy: (i) the criteria for the definition of alloformations conform with the formally defined stratigraphical procedures ([NACSN, 1983](#)); (ii) alloformations are three-dimensional bodies of sediment whose deposits are genetically associated with a given meander belt created during a discrete time interval; (iii) each alloformation contains a set of heterogeneous sedimentary deposits and their evaluation can be related to a set of fluvial processes; and (iv) this approach to geologic mapping establishes a relative chronology for the units identified.

[Autin \(1992\)](#) concluded that if alternatives to the allostratigraphical approach are adopted, then interpretations of some floodplain fluvial sequences are limited. For example, [Autin \(1992\)](#) argued that while a morphostratigraphical approach may enable the association between constructional landscapes

and sedimentary deposits to be inferred, a three-dimensional sediment body is not delineated. In addition, if sediment units are treated as lithostratigraphical units, the formations would reflect depositional processes and environments but would provide little or no information regarding valley chronology and evolution. Subsequent work in Mississippi Valley of Louisiana has utilized allostratigraphy, lithostratigraphy, and pedostratigraphy depending on the specific problem being addressed (e.g., [Autin, 1996](#); [Heinrich, 2006](#); [McCulloh et al., 2003](#)).

Morphostratigraphy and Allostratigraphy in Practice

Morphostratigraphy and allostratigraphy play a fundamental role in geomorphology and Quaternary stratigraphy ([Hughes, 2010](#)). Several geological surveys in the United States, such as Louisiana ([Heinrich, 2006](#); [McCulloh et al., 2003](#)), Idaho ([Breckenridge et al., 2005](#)), and other state Geological Surveys utilize allostratigraphy to subdivide Quaternary deposits. However, elsewhere, morpho- and, especially lithostratigraphy, has dominated. This is probably because allostratigraphy is a relatively newer concept, first appearing in 1983 in the *North American Stratigraphic Code* ([NACSN, 1983](#)). Allostratigraphy is rarely applied in some countries, such as the United Kingdom, for example, where the British Geological Survey employs lithostratigraphy to subdivide the Quaternary stratigraphical record (e.g., [McMillan et al., 2005](#)).

Some have argued that morphostratigraphical units should have no formal stratigraphical status and that they should not be applied with any formal stratigraphical implication (e.g., [Bowen, 1978](#); [Rawson et al., 2002](#), pp. 11–12; [Richmond, 1959](#)). However, in practice, morphostratigraphical units are rarely defined without using at least some lithological criteria ([Bowen, 1978](#), p. 94). The fact that morphological and lithological criteria are often used to describe and subdivide glacial sediments led [Hughes et al. \(2005\)](#) to argue for the integration of morphostratigraphy within lithostratigraphy. [Räsänen et al. \(2009\)](#) made a similar argument for the integration of allostratigraphy and lithostratigraphy when dealing with glacial deposits. In fact, there is a clear consensus that whether morphostratigraphy or allostratigraphy is adopted to subdivide and order any type of Quaternary deposits, each is always best applied in conjunction with lithostratigraphy ([Hughes, 2010](#); [Räsänen et al., 2009](#)).

Pedostratigraphy

A Palmer, Massey University, Palmerston North, New Zealand

Introduction

Landscapes comprise diverse landforms, parent materials of different composition, and geomorphic surfaces formed by erosional and depositional events, all of various ages. Landscapes can evolve rapidly at various times in response to both long-period climatic cycles and tectonics, and relatively instantaneous events such as storms and earthquakes. At other times and locations, landscape evolution is slow, and driven by more benign processes of background erosion rates, dust accretion, and weathering. Consequently, soils can form continuously through long periods of landscape evolution, and/or they can form rapidly following catastrophic events.

Pedostratigraphy can be defined as the study of the stratigraphical and spatial relationships and implications of surface and buried soils (adapted from Wysocki et al., 2005).

In the current landscape, soils form in a variety of environmental conditions, which can be analyzed by the classic equation formulated by Dokuchaev and Jenny: $S=f$ (climate, vegetation and organisms, relief, parent material, and time).

Past landscapes and their soils, whether buried or still at the surface, can be analyzed in exactly the same way, except that here the effects of burial or exhumation must also be considered. Therefore, landscapes contain soils of different morphology reflecting the environment in which they formed. Inevitably, these soils will continue to form, aggrade through slow sediment accretion, be truncated by erosion, or be buried. However, more complicated, and perhaps more sophisticated, models have also been put forward (Follmer, 1998), because in the Dokuchaev analysis it is difficult to integrate the effects of changing climates and vegetation, let alone the hydrological changes that take place as a soil is variously weathered, buried, or exhumed.

Soil scientists have begun to realize that soil genesis can involve many specific and complex processes (Follmer, 1998) under the imprint of environmental conditions that prevail at each moment in time. The induced weathering can then set up pedogenic pathways where the properties of adjacent soils may diverge, and then continue to diverge, run a parallel course, or converge once more. Once a soil is buried, these relationships become more complicated.

Definitions

A paleosol is a soil formed in a landscape of the past, and may be buried, nonburied or exhumed. Buried soils represent periods of slow or nil deposition and slow or nil erosion reacting to the environmental conditions of the time and through subsequent centuries. Because landscapes consist of different surfaces on many kinds of deposits, a soil may be independent of the deposits into which it forms (Catt, 1986). Thus, soils can form 'soil stratigraphic' (or 'pedostratigraphic') units in exactly the same way that 'lithostratigraphic,' 'chronostratigraphic,' and other stratigraphic units are recognized and defined. The

North American Stratigraphic Code (1983) defines a pedostratigraphic unit as 'a buried, traceable, three-dimensional (3D) body of rock that consists of one or more differentiated pedologic horizons.'

A pedostratigraphic unit is a body of sediment or rock that consists of one or more pedological horizons that developed in one or more lithostratigraphic, allostratigraphic, or lithodemic units. These units are distinguished by the presence of one or more pedologic horizons that display clear signs of soil formation (pedogenesis). All the morphological features that are used to recognize surface soils can be applied to buried soils as well (Table 1), but the apparent absence of a feature is not an indication that no buried soil is present. For example, soil organic matter can disappear in buried oxidized sediments, and soil structure is often destroyed postburial.

The upper boundary of a pedostratigraphic unit is defined in the code as being the top of the 'uppermost pedologic horizon formed by pedogenesis in a buried soil horizon,' and the lower boundary is the lower boundary of a horizon with definite pedogenic features. These requirements become problematical in entirely weathered sequences, and in upbuilding soil profiles, for example, soil formation continuing through slow loess accretion. Pedostratigraphic units are different from surface soils in two important ways. A soil forming at the surface is taken to include overlying plant litter layers or peat and carbonaceous deposits. These are specifically excluded from pedostratigraphic units, but they may be defined as lithostratigraphic or biostratigraphic units. Also, the parent material C horizon, where present, is usually included in the profile of a surface soil whereas the code, requiring the recognition of definite morphological features for inclusion in a pedostratigraphic unit, often excludes C horizons.

Although the definition of a pedostratigraphic unit in the code requires 'traceability,' few buried soils are continuously traceable for long distances. Because they represent a ground surface, they just as often undergo erosion, or changes in character, as the surface soil mantle does.

Pedostratigraphic units are unique in that they are a product of alteration at or near the surface of the earth. Their lithology and other physical, chemical, and mineralogical properties can, because of this alteration, differ markedly from those of the parent material. Like magneto- and chronostratigraphic units, a single pedostratigraphic unit may be defined in many different parent materials of diverse composition and age. However, unlike the former two stratigraphic units, pedostratigraphic units are independent of time concepts and may be diachronous, yet they may carry significant evidence of age.

Selected Milestones in Pedostratigraphy

Buried soils have been recognized in Quaternary deposits since 1873 when A. H. Worthen of the Illinois Geological Survey

Table 1 Selected morphological, physical and, chemical pedogenic features, their implications, and potential for preservation in paleosols

<i>Pedogenic feature</i>	<i>Implication</i>	<i>Weathering</i>	<i>Preservation potential</i>
<i>Morphological</i>			
Color	Liberation of iron oxides	Weak–strong	High
Organic matter	Prolonged plant growth	Weak–strong	Low
Soil structure	Prolonged plant growth	Weak–strong	Moderate
Clay formation	Moderate weathering; wetting and drying	Moderate–strong	High
Clay coatings	Clay movement	Moderate–strong	High
Carbonate concretions	Leaching	Weak–strong	Moderate
Fragipan	Wetting and drying	Moderate	Low
Root traces	Plant growth and root exploration	Weak–strong	High
<i>Micromorphological</i>			
Argillans	Clay movement	Moderate–strong	High
Fabric development	Pedological ‘organization’	Moderate–strong	Moderate
<i>Chemical</i>			
Lower pH and BS%	Leaching	Weak–strong	Low
Depletion in K ₂ O	Leaching, plant uptake, weathering	Moderate–strong	High
Forms and amounts of P	Plant uptake and return, clay movement, leaching	Moderate–strong	High
<i>Physical</i>			
Lower dry bulk density	Formation of soil structure, burrowing by organisms	Moderate–strong	High
Increased macroporosity	Formation of soil structure, plant root channels, burrowing by earthworms	Moderate–strong	Moderate
Increased plant available water	Formation of soil structure, plant root channels, weathering, organic matter	Moderate–strong	Moderate

showed that a humus-rich soil had developed on one till before being buried by another. In doing so, he established not only the stratigraphic value of buried soils, but also their paleoclimatological value. Thus, the recognition of buried soils was instrumental in developing the glacial stratigraphy of North America, and later, central Europe.

Modern concepts of pedostratigraphy were introduced in pioneering works by [Butler \(1959\)](#), [Ruhe \(1956\)](#), [Ruhe \(1969\)](#), [Morrison \(1964a\)](#), [Morrison \(1964b\)](#), and [Morrison \(1978\)](#).

[Ruhe \(1956\)](#) defined a geomorphic surface as ‘a portion of the land surface that is specifically defined in space and time. It may occupy many parts of the landscape and may include many landforms.’ A geomorphic surface is a spatial time plane linking erosional, soil forming, and depositional parts of the land surface. Soil-forming parts of the landscape need to be metastable long enough to form at least an A horizon, although the transition to erosional areas can be marked by exposed B (subsoil) horizons, while transition areas to deposition are marked by aggrading A (topsoil) horizons. Buried geomorphic surfaces are common in tectonically and volcanically active areas where landforms are episodically mantled by tephra, loess, or dune sands ([Tonkin, 1994](#)), and in areas of growing overlapping fans and valley fills.

Referring to geomorphic surfaces as ‘time planes’ can be misleading because they are rarely as instantaneous as a tephra ([Figure 1](#)), a lahar, or a flood deposit, for example. Usually, the metastable phase is exactly as the name suggests, with an array of soils of slightly different age on different elements of the surface, and different rates and spatial location of erosion and deposition elsewhere. Thus, geomorphic surfaces, both at the surface and buried, are often somewhat diachronous.

[Butler \(1959\)](#) recognized that erosion and deposition cycles can be episodic, for instance, driven by climate change. Periods of metastability, during which recognizable soils develop, are

followed by instability that creates erosional and depositional surfaces. Together, the metastable and unstable phases constitute a ‘K-cycle.’ K-cycles are best recognized in hill country, rather than continuously eroding steep land, where the soil-residence time is long enough for clearly defined soils to develop before being eroded or buried.

A seminal application and development of new concepts in pedostratigraphy was made by [Morrison \(1964a\)](#) while working on the Lahontan and Bonneville pluvial-lake sequences in the Great Basin of the US. He found that paleosols are the best records of metastability in landscape evolution and are, thus, important parts of the stratigraphic record.

Where geomorphic surfaces are buried by varying depths of sediment, a number of possible soil-stratigraphic scenarios arise ([Morrison, 1978](#)) and these have subsequently been recognized as soil profile forms by [Tonkin \(1994\)](#). Simple soil profile forms have no buried soil features to some arbitrarily defined depth, which Tonkin takes as 2 m but which others (e.g., [Hewitt 1998](#)) might take as 1 m. Truncated soil profile forms have lost upper horizons to erosion. An A or E horizon might be found developing in former subsoil horizons. Aggrading soil profile forms have thick A horizons and B horizons that preserve the morphological features of once having been formed at the surface ([Figure 2](#)).

Composite soil profiles develop in thin accessions of sediment where rapid repetitions of A, E, or B horizons are temporarily preserved to form bi- or polysequel soils. The ultimate fate of such soils, if they are preserved, is usually to become welded into a single soil whose complex history might be difficult to unravel. Good examples of such soils can be found in thin accessions of ash surrounding volcanoes ([Figure 3](#)).

Compound soil profile forms are also bi- or polygenetic, but an interval of less weathered parent material is preserved

Figure 1 The Mamaku Plateau west of Rotorua in the North Island of New Zealand was formed by the eruption of the Mamaku Ignimbrite 230 ka. The plateau has been episodically partially mantled and partially stripped of loess and tephra since its formation, resulting in an array of buried and geomorphic surfaces, defined by erosion surfaces and/or soils. (a) An oblique aerial view. Note the prominent erosional remnants or tors up to 20 m high (photograph by author). (b) A section through a tor on the central and highest part of the plateau. The ignimbrite here is overlain by a tephra mantle less than 15 000-cal years old. Any older loess, tephra, and soils were stripped by wind, fluvial, and frost action during the last glaciation. Elsewhere on the plateau, fragments of the complete loess and tephra record are preserved between erosion surfaces. Complete sections representing 230 000 years of accumulation occur on the margins of the plateau (photograph by author).

between the surface and buried soils that is less likely to be obscured by weathering, at least in the short term. Episodic accumulation of lapilli-grade tephra from andesite and rhyolite tephra are good examples (Figure 4).

Figure 2 Loess and paleosols near Wanganui, southwestern North Island, New Zealand. The site is a 300 ka marine terrace mapped by Pillans (1990), who appears in the photograph. The prominent ginger paleosol is the Last Interglacial soil complex formed by three soil-forming phases representing marine oxygen isotope stages 5e, 5c and 5a. Loess and tephra continued to accumulate slowly during the formation of this soil, and it is a good example of an aggrading profile. Above the thick ginger soil complex are three more loess units separated by weaker soils (photograph by author).

Persistent profile forms (Tonkin, 1994) are soils that maintain a similar morphology over significant periods of time, and any two soils may be of vastly different age, yet have similar morphological properties. Spodosols and ultisols often persist without apparent change for long periods of time.

The pioneering works of Ruhe (1956) and Butler (1959), and Morrison (1964a) and Morrison (1964b) reawakened interest in paleopedology and pedostratigraphy in the soil science and Quaternary science communities. In 1965, paleopedology became a commission of the International Quaternary Association (INQUA) and a working group of the International Society of Soil Science. The two societies sponsored the 'First International Symposium on Paleopedology' in Amsterdam in 1970. The meeting brought together scientists from a wide range of disciplines from geology and geomorphology to agriculture. From this meeting, a selection of papers was published in a book edited by Yaalon (1971).

Figure 3 The Tirau soil, west of Rotorua, New Zealand, is developed in thin, distal accessions of rhyolite ash, and is an example of a composite soil. The scientist pictured is Alan Pullar, who, with Colin Vucetich (Figure 4) was largely responsible for detailing the tephrostratigraphy of the Central North Island of New Zealand (Vucetich and Pullar, 1969). At shin level is the 26.5 ka (cal) Kawakawa Tephra erupted from Lake Taupo, which rests on a weak paleosol formed 30–50 ka. Above the Kawakawa Tephra, is volcanic loess weakly weathered to form a B horizon, containing two more thin rhyolite tephras. At Pullar's hand level is the Rerewhakaaitu Tephra ca. 17 ka (cal). At this level and above, pedogenic features become more pronounced in response to late Pleistocene warming and warm, humid Holocene conditions. There is no loess above this level, and the soil is developed in a major tephra at ca. 14 ka, followed by several thinner ones on the surface. This is also a good example of an upbuilding profile. Each B horizon was once an A horizon at or near the soil surface (photograph by J. A. Pollok).

Problems with Nomenclature

It is not surprising that scientists trained in different aspects of geology, geomorphology, soil science, and agriculture, all working on aspects of pedostratigraphy and paleosols, should have different views, methods, and nomenclatures. Nonetheless, disagreements over nomenclature have been a persistent problem in pedostratigraphy and paleopedology. A Paleopedology Manual (Catt, 1990) was produced to describe methods used in the study and interpretation of paleosols,

Figure 4 The Taupo soil, north of Lake Taupo, New Zealand, is developed in thick deposits of Taupo Tephra (dates are in radiocarbon years). Beneath are a succession of rhyolite tephra erupted from Lake Taupo (Waimihia and Opepe) and the Rotorua region (Whakatane, Rotoma, Waiohau and Rotorua). Each is thick enough for a thin C horizon to be preserved, and this is an example of a compound profile. The person is Colin Vucetich, mentioned in Figure 3 (photograph by J. A. Pollok).

but it did not address the conflicts in nomenclature. The Second International Symposium on Paleopedology, which was held in 1993, sought to address conflicts regarding terminology, definitions, classification, and genetic interpretations (Follmer, 1998). The submissions were published via four Paleopedology Commission newsletters (Follmer, 1995).

A distinction is often made between buried paleosols and relict paleosols. The latter are paleosols formed on old geomorphic surfaces such as moraines, terraces, and fans, and other metastable landforms, which began forming when soil-forming conditions were different from those of the present day, but were still developing close to the ground surface. The debate (Bronger and Catt, 1998; Morrison, 1998) is over the extent to which all surface soils are in some way relict, especially those that began forming prior to the Holocene. Catt (1998) suggests that the term 'relict' has become obsolete and favors simply 'paleosol.' Nonburied paleosols should show distinct evidence that the environment of soil development was different from the present. Johnson (1998) argues that the term paleosol should be used for

buried soils, not surface soils on the ground, as all surface soils are always being subjected to modification in an ever-changing environment. Holliday (1998) questions the need for the term 'paleosol,' preferring to use simply 'soil' and 'buried soil.' He suggests reserving the term paleosol to soils that are lithified throughout their profile. Others have suggested putting minimum age limits on paleosols (Bronger and Catt, 1998), for example, older than the Holocene. Such proposals have met with protest because there are numerous examples of paleosols in Holocene-aged deposits that have formed on ancient landscapes, for example, the paleosols on alluvium on the Mississippi floodplain (Aslan and Autin, 1998).

The 'geosol' was introduced and defined by Morrison (1964b) and Morrison (1967) as the term for a pedostratigraphic unit, because he found that paleosols are significant elements of the stratigraphic record deserving recognition and classification.

Geosols

A geosol is defined (Catt, 1998) as a 'traceable, mappable 3D body of soil material comprising one or more differentiated pedologic horizons; it has a consistent stratigraphic position and is defined at a type locality where the horizons are buried by younger deposits, but may be traced to sites where it crops out on the present land surface. Geosols may or may not transgress lithostratigraphic, allostratigraphic, or lithodemic units. They change laterally in response to differences in parent material, the original buried topography, drainage, vegetation, and other factors, giving different pedofacies. Geosols may be monogenetic, polygenetic, or compound (multistory). Compound geosols (pedocomplexes) comprise two or more soils (pedomembers), which are separated over large areas by thin unmodified deposits or by unconformities; they often merge laterally into polygenetic geosols'.

Therefore, geosols may be regarded not just as soils or paleosols, but as soilscapes that can be recognized as laterally extensive stratigraphic horizons (Morrison, 1978). The term has been questioned by some (e.g., Holliday (1998)) for not clarifying soil stratigraphic issues, and lacking utility and application. Retallack (1998) also points to situations when the use of geosol is not appropriate. Many alluvial sedimentary sequences, particularly on fans, can have literally hundreds of buried soils, of different character and limited traceability. Each soil may be truncated by a paleochannel or merge with other buried soils. These cannot easily be named and characterized as geosols. In this situation, it is more useful to describe and categorize the different types of buried soil, and he suggests the name 'pedotype' for this eventuality.

Although accepted in the North American Stratigraphic Code (1983) as the fundamental and only pedostratigraphic unit, the International Stratigraphic Guide (1994) has yet to adopt the term, and in fact includes no soil stratigraphic units.

The Application of Pedostratigraphy to Paleoclimatology and Correlation

Eastern European Loess

In the 1960s and 1970s, the loess sequences of central Europe were studied intensively. In what is now the Czech Republic

and Slovakia, Kukla and Koci (1972) and Kukla (1975) described multiple buried soil-loess cycles in deposits on hillsides and river terraces. Their cycle begins with rapid warming from cold and arid climate conditions in which calcareous loess is generated, to temperate moister conditions generating colluvial sediments from hillsides and terrace risers, the boundary they called a 'markline.' During warm interglacial conditions, a decalcified brown forest soil develops through the colluvium into the loess below, although the markline remains decipherable. Deteriorating climate sees cold climate loess deposited once more. Morphological evidence of the multiple glacial cycles was supported by attendant variations in snail faunas (Lozek, 1969). These cycles became known through Europe as 'pedocomplexes.' At favorable sites, the cycles could be subdivided into stadial cycles of relatively warm and humid conditions versus cycles of cold and dry conditions.

Paleomagnetic studies by Koci (reported in Kukla, 1975) showed that sequences, in particular the Cervený Kopec section near Brno, extended well below the Brunhes-Matuyama paleomagnetic boundary (~0.78 Ma).

It became clear that the alpine and continental glacial stratigraphy are only a partial record of climate change during the Quaternary. The oxygen-isotope stratigraphy of deep-ocean cores preserves a much better record of fluctuating Quaternary climate. Recognizing that the marklines representing rapid postglacial warming in the loess sequences were similar to 'terminations' representing similar rapid warming in the oceanic record, Kukla (1975, 1987) was able to provide a convincing continent to deep ocean climostratigraphic correlation for the last million years.

The Loess Plateau of China

The loess-paleosol sequences of the Loess Plateau of China rank as the most complete record of terrestrial climate change during the extended Quaternary period (the past 2.5 Ma). Loess-paleosol sequences over 150-m thick are common in the area enclosed by the big bend of the Huang He River north and west of Xian. The loess is coarse and sandy close to its source in the deserts of the northwestern part of the region, and becomes finer textured and more weathered in the moister southeastern part of the region. It is here, in sections such as Baoji (Ding et al., 1991), that the intervening paleosols become more prominent (Figure 5).

Magnetostratigraphy, and in particular magnetic susceptibility, has proven to be the tool that enabled the deep loess-paleosol sequences, first in Europe and then in China (Kukla, 1987; Liu et al., 1987), to be correlated to the marine oxygen isotope record. Initially only the major glacial-interglacial cycles were correlated, but now more detailed correlations of intervening, minor paleosols are made (Ding et al., 1991). There is still considerable debate as to the origin of the magnetic susceptibility signal. It might be an effect of dilution, where very fine magnetic particles form a constant aerosolic rain, but are relatively diluted by coarse nonmagnetic loess particles during glacial periods. Others have shown that at least part of the signal is due to the formation of fine-grained ferromagnetic particles during pedogenesis.

Soil morphology and micromorphology, used in conjunction with pollen and phytolith studies, are able to distinguish

Figure 5 The Luoquan loess section, Loess Plateau, China. The view shows the upper 50 m of the almost 200 m loess thickness. The prominent paleosol in the middle of the image is S5 (ca. 550 ka) with S4-S1 faintly visible above (photograph by Brad Pillans).

between full forest Alfisols in interglacials, and Mollisols and Inceptisols formed during interstadial weathering.

Beneath the main loess sequence in China is an extensive deposit called the Red Clay, which has now also been shown to be loess (Ding et al., 2000). The Red Clay was deposited between 7 and 2.6 Ma and was transported by westerly winds from dust-source regions in Northwestern China. At 2.6 Ma, a major shift in atmospheric circulation took place, and loess was instead deposited by northerly winds during the winter monsoon.

More detailed paleoclimatic studies are now appearing in which the pedostratigraphy of the Chinese loess deposits is being used to follow the history and variability of the East Asian paleomonsoon climate (e.g., An, 2000). Chinese scientists and their collaborators from the west lead the world in the study of loess–paleosol sequences and their climatic interpretation.

Palouse Loess, Northwestern USA

In the Palouse region of the Pacific Northwest of the USA, Busacca et al. (1992) and McDonald and Busacca (1992) provide a pedostratigraphic framework of loess accumulation, soils, tephra, and paleoclimate. The Palouse loess and paleosols are interesting for several reasons. First, they contain both petrocalcic (cemented by calcite) and duripans (cemented by silica), and their formation complicates the morphology and interpretation of paleosols. Second, their Washtucna paleosol apparently formed at the height of the Last Glacial Maximum, when mean accumulation rates of loess were lower rather than higher (Sweeney et al., 2005) because of the configuration of the then prevailing anticyclones. Glacial outburst floods then provided a ready source of material for more rapid

accumulation in the Late Glacial. Accumulation rates decreased in arid conditions just prior to the Holocene allowing the Sand Hills Coulee soil to form. Accumulation at a slow rate resumed in the Holocene. The Washtucna paleosol is also remarkable for an intense concentration of cicada burrows. O’Geen and Busacca (2001) showed that these cicadas were associated with sagebrush, and that this vegetation must have been dominant at the time. These studies prove the value of pedostratigraphy in challenging the established paradigm of loess accumulation during glacials and soil formation during interglacials.

The pedostratigraphy of the Palouse loess also illustrates the effects of soil formation during sediment accumulation, and that each paleosol has features inherited from upbuilding. Thus A horizons gradually become B horizons as slow loess accretion continues. This effect is probably the rule rather than the exception in many sedimentary environments. Even where loess accumulation has been very slow, in an extreme leaching and weathering environment on the super-humid West Coast of the South Island of New Zealand, Almond and Tonkin (1999) describe the pedogenesis of soils as being by upbuilding rather than from the surface downwards.

Loess in the Southern North Island of New Zealand

In the southern North Island of New Zealand, loess is widespread on Quaternary terraces formed in the last 500 ka. The general model for the deposition of this loess is that during cold climates erosion is maximized, rivers aggrade, and dust is blown from the aggrading flood plain and deposited as loess on higher surfaces (Vella, 1963). During warm climates the land surface is more stable, rivers degrade, soils develop in the loess, and marine terraces are cut by high sea levels (Palmer and Pillans, 1996). Most of the loess is quartzofeldspathic and

is derived from Mesozoic greywacke-argillite rocks, and Plio-Pleistocene mudstones and sandstones. However, there is also a significant input of both tephra and tephric loess from andesite and rhyolite volcanoes in the north of the district (Palmer and Pillans, 1996). Quartzofeldspathic loess dominates in the particularly cold glacials when erosion in the hinterland was at a maximum. The soils between loess units are characterized by upbuilding profiles of slow loess accumulation and tephra accretion (Lowe et al., 2008b).

Each loess can be matched to a river aggradation surface from which it was derived. Each major paleosol formed in a full interglacial is matched by a marine terrace. Less significant soils formed during interstadials when rivers temporarily degraded and the loess supply slowed.

Laboratory Studies

It is not always possible to infer taxonomic and paleoclimatic information from the morphology of paleosols alone. For example, progressive oxidation of organic matter in loess paleosols often confounds their classification and interpretation. Soils, decalcified during formation, are frequently recalcified with carbonate derived from overlying loess (Bronger, 2003). Micromorphology can detect A horizon fabrics, distinguish between primary and secondary carbonate (Bronger, 2003), and provide clear evidence of clay illuviation in the form of argillans (Brewer, 1964; Catt, 1990).

The intensity of weathering that soils have undergone can be assessed using both the amount and ratios of elements and oxides. Runge et al. (1974) used forms and amounts of phosphorus to identify paleosols in loess in the South Island of New Zealand. Their results show that both total and plant available forms of P are reduced in the B horizons of paleosols due to plant uptake and leaching, although a certain amount is returned to topsoil horizons by plant roots and litter. Childs (1975) used element distributions in New Zealand loess to confirm the location of paleosols. For quartzofeldspathic loess, he found that the distribution of Al, Si, and Zr provide evidence for uniformity of composition, while the depletion of P, K, and Ca indicated paleosols. In North Island loess containing tephra, he found that Si also became mobile (due to formation of allophane) indicating paleosols.

Molar ratios are also commonly used. For example, Rutter et al. (1978) used silica:sesquioxide and potassium:silica ratios to differentiate three paleosols in the Central Yukon. In tephric and quartzofeldspathic loess in the North Island of New Zealand, Palmer and Pillans (1996) used dry bulk density, percent quartz, magnetic susceptibility, and potassium distribution to study a loess-paleosol sequence dating back to 0.5 Ma.

Tephra Sequences

Tephra are time markers of events in volcanic eruptions, landscape evolution, paleoclimate, natural hazards and archaeology in many parts of the world, particularly near plate boundaries where volcanoes are more common (Lowe et al., 2008a). However, rhyolitic and dacitic tephras, in particular, can also be found many hundreds of kilometers from source. Soils that form on these tephras record information of relative stability and

paleoclimate. Textural and mineralogical differences between tephras in any sequence can make interpretation and pedostratigraphy difficult and it is usually important to study both proximal and distal sections. The sequence near Taupo, New Zealand (Figure 4), is an example of a proximal section of some of the tephras shown, whereas the section in Figure 3 is distal. The rate of soil formation in each deposit is a function of texture, climate, and mineralogy. It should be noted that because tephras are dispersed in different directions from source due to different wind directions, and are from different sources, the two sites illustrated do not contain the same tephras.

The amount of weathering and the extent of soil formation of each paleosol depend on climate (Figure 3) and the quiescent period between eruptions. In buried Andisols in Japan, Watanabe et al. (1998) found that the most developed Holocene paleosols, characterized by humus accumulation and allophane formation, formed in the Holocene Climatic Optimum. Younger paleosols show less weathering regardless of the time available for formation. The most important influence on the weathering products of tephras and tephra sequences is the silica concentration in the soil solution and the availability of aluminum to co-precipitate (Lowe, 1986). It is the balance between rainfall, drainage, tephra thickness, and depth of burial by further tephra and/or loess accretions that influences the formation of either allophane or halloysite. Conditions that favor allophane and imogolite formation include higher more evenly distributed rainfall (generally 1200 mm or more and few dry periods in summer); rapid drainage facilitating Si leaching; less influence of the organic cycle; shallow burial depth; and andesitic or basaltic (higher Al:Si) rather than rhyolitic composition. The opposite weathering conditions favor halloysite formation. Lowe (1986) found the length of weathering time to be subordinate, although tephric paleosols older than 350,000 years tend to be dominated by halloysite.

Tephra and paleosol sequences have also proven to be favorable repositories for opal phytoliths from plants. Kondo et al. (1994) examined phytoliths from tephra/loess/paleosol sequences in the North Island of New Zealand (one was close, and similar to the section shown in Figure 2). They found that phytoliths characteristic of grass or shrubs dominated parts of the sequences deposited in glacial periods while forest-derived phytoliths were dominant in the interglacial and interstadial periods.

Alluvial Sequences

Paleosols are a common feature of alluvial sequences, particularly in areas of tectonic subsidence or where rapid sedimentation or river avulsion has taken place both in Quaternary and ancient settings (Srivastava et al., 2010). Models of fluvial sedimentation are useful for interpreting paleosols in alluvial sequences (Aslan and Autin, 1998; Kraus, 2002). In each case, the paleosols inform paleoclimate and paleoenvironment although textural and compositional differences between soil parent materials may complicate interpretations. The carbon that is sometimes preserved in Holocene to late Pleistocene paleosols can be dated to provide a chronostratigraphy (e.g., Hall and Periman, 2007).

Figure 6 (a) The Ruahine fault, eastern North Island, New Zealand. The fault has dextral movement at $3\text{--}4\text{ mm year}^{-1}$, and is just one of several major strike-slip faults in the region. To the left (west) is Mesozoic greywacke-argillite and to the right (east) is Pliocene marine mudstone and limestone. Long-term uplift has been to the west, but more recent earthquakes in the Holocene have uplifted the eastern side. The fault trench affords excellent opportunities to study the magnitude and offset caused by earthquakes on the fault by excavating a trench with a digger (photograph by Vince Neall). (b) The main fault plane is clearly seen within the fault trench separating peaty paleosols and tephra (left) from blue-gray uplifted Pliocene mudstone (right). The upper black peaty paleosol formed on top of the Taupo Tephra (see [Figure 4](#)) and the second paleosol formed on the Waimihia Tephra. Soil formation on the Taupo Tephra was interrupted by deposition of greywacke and mudstone rubble following an earthquake. The history of fault movement can be pieced together by careful study of the fault trench, using tephrochronology, and radiocarbon dating of organic matter. Vertical strings and yellow dots are 1 m apart (photograph by Vince Neall).

Fans

Soils and paleosols preserved on and within alluvial, colluvial, and debris flow fans provide information on periods of fan building both spatially and temporally ([Carboni et al., 2006](#); [Srivastava et al., 2009](#)). In some environments, their carbon provides the only material dateable by the radiocarbon method. [Bennett et al. \(2006\)](#) found that laterally extensive

paleosols on fans in San Joaquin valley, California, marked sequence boundaries, in keeping with sequence stratigraphic models of fan growth. They found that ground-penetrating radar was able to image the paleosols, which are interrupted by numerous channels and channel deposits. In the Himalayan region, debris flow and alluvial fans preserve paleosols, which enables chronostratigraphic interpretation ([Srivastava](#)

et al., 2009). Loess cover on the fans preserves strongly developed paleosols and fluvial deposits preserve weakly developed paleosols in response to tectonics and climate change.

Fault Trenches

In studies of paleoseismicity, trenches are cut across fault lines and fault scarps where the geomorphic setting of the site favors sedimentation that has buried and preserved the evidence of past earthquakes (Figure 6). Pedostratigraphy is vital for a full understanding of events, rates, and chronology. Soils and peat layers preserved in fault trenches can provide evidence of quiescent periods between earthquakes and may be dated to provide limiting ages for fault movement. Fresh slope, alluvial, or colluvial deposits that bury soils can indicate a seismic event, although care must be taken to eliminate the possibility of storm or normal slope deposits. The stratigraphic relationships and offset of the paleosol and other deposits in the fault trench are then used to reconstruct a seismic history (e.g., Dolan et al., 2000; Langridge et al., 2003; Schermer et al., 2004).

Geoarchaeology

Pedostratigraphy is a vital tool when interpreting geology and archaeology of past civilizations. It may be used in both relatively short and long time periods. Butzer (2004) describes multiple paleosols in coastal eolian sands in the southwest of South Africa, dating back to Marine Oxygen Isotope 9, which preserve records of human occupation, their activities, and the foods they ate. The paleosols range from simple soils with weathered B horizons to calcretes or plinthite depending on the climate in which they formed and the temporal stability of the site. In Greece, red soils and paleosols (mostly Alfisols) developed in alluvium form chronosequences that span more than 200 000 years and are useful in interpreting human history of the region (van Andel, 1998). The degree of soil formation is linked to their age. At Pompeii, the soils buried by products of the cataclysmic eruption of AD 79 were rich volcanic soils that drew people to the area for agriculture. Their artifacts, buildings, and bodies are preserved on that ancient land surface (e.g., Jashemski and Meyer, 2002). Paleosols that developed in older volcanic deposits reveal a history of at least six Plinian eruptions in the last 17 000 years, some preserving evidence of human occupation.

Conclusions

Pedostratigraphy is the study of the stratigraphy, spatial relationships, and implications of surface and buried soils. A paleosol is a soil formed in a landscape of the past, and may be buried, nonburied, or exhumed. Buried soils may have the status of pedostratigraphic units, recognized in the North American Stratigraphic Code.

Pedostratigraphy gained impetus in a series of seminal studies in the 1950s and 1960s where it was used to good effect in landscape models that are widely quoted even today. These studies found that paleosols are the best records of metastability in landscape evolution, and are thus important parts of the stratigraphic record. However, scientists have had difficulty in

agreeing on a common nomenclature for use in pedostratigraphy, and this is probably a reflection of the use of pedostratigraphy by Quaternary scientists from different specializations for a variety of applications.

Pedostratigraphy has been used to best effect in the study of loess–paleosol sequences. It was first demonstrated in Europe that the loess sequences contained multiple soils, and that these soil–loess pairs represented many more fluctuations in climate than suggested by the record of Alpine glaciation. The multiple fluctuations in climate inevitably drew comparison with the oxygen isotope record of the deep sea. The application of magnetostratigraphy and magnetic susceptibility confirmed the correlation, leading to advanced and detailed land–ocean correlations, particularly in China.

Pedostratigraphy is also informative in a number of other settings where paleosols are useful in interpreting the geological and geomorphic setting and paleoclimate. Examples include tephra and alluvial sequences, fans, and fault trenches. Pedostratigraphy is also embraced by geoarchaeologists who need to understand the stratigraphy and environment of past civilizations.

Introduction

Sedimentary cyclicity is an intrinsic feature of marine sedimentary basins, and is controlled by relative sea-level change resulting from the interplay of tectonics, sediment supply, and eustasy (Miall, 1997). Higher frequency cycles of glacio-eustatic origin have periodicities of tens or hundreds of thousands of years. Lower frequency cycles are millions to hundreds of millions of years in length and are driven by sea-level changes tied ultimately to plate tectonic movements.

Seismic reflection images of continental margins depict unconformity-bounded sedimentary cycles with an internal arrangement of reflectors that correspond to stratal surfaces (=depositional surface of shelf margin) (Mitchum et al., 1977). In profile, the stratal architecture of sedimentary cyclicity is revealed on a basin-wide scale, and its development can be tracked across many successive cycles of relative sea-level change. Mitchum et al. (1977) termed individual cycles of this type 'third-order seismic sequences,' where a sequence is defined as "a stratigraphic unit composed of a relatively conformable succession of genetically related strata and bounded at its top and base by unconformities or their correlative conformities."

Historic studies of cyclic Quaternary sediments grouped repetitive faunal and lithological facies into units termed 'cyclothem' (Fleming, 1953; Vella, 1963), and stratal relationships within similarly cyclic sequences were later inferred using outcrop sedimentary facies analysis (Loutit et al., 1988; van Wagoner et al., 1990). Since the late 1980s, a modern sequence stratigraphic approach has been applied successfully to cyclic outcrop successions of Quaternary age (Abbott and Carter, 1994; Ito, 1992; Naish and Kamp, 2007), in which a much higher stratal resolution (down to centimeters) can be differentiated than is the case for conventional seismic analysis. Following the seismic work of Payton et al. (1977) and Vail et al. (1987), seismic sequences have become variously known as stratigraphic sequences, depositional sequences, or (as used herein) sequences.

Clarity of thought is aided by drawing a clear distinction between a sequence stratigraphic model (SSM) – which summarizes the geometric stratal relationships of sediments deposited during a single major cycle of sea-level change – and a global sea-level model (GSM), which hypothesizes a sea-level curve for past times (Carter and Naish, 1998; Carter et al., 1991). A major aspect of classic sequence stratigraphy (Payton, 1977) was the development of techniques whereby a sea-level curve could be reconstructed from geometric analysis of sequences on seismic profiles, which led to the widely used sea-level curves of Vail et al. (1977) and Haq et al. (1987). Such studies contain an inescapable element of circular reasoning, and it is the single greatest strength of Quaternary sequence

stratigraphic studies that they are made against the independent, and now well-tested, model of sea-level variation that is provided by oceanic oxygen isotope measurements (e.g., Shackleton et al., 1990; Lisiecki and Raymo, 2006).

Sequence Stratigraphic Models

An SSM is a summary of the stratal architecture and facies composition that occur within a sequence (Carter et al., 1991). The stratal patterns and sedimentary environments that define the architecture of the classic SSM of Payton et al. (1977) and Vail et al. (1987) are depicted in Figure 1. Between bounding disconformities formed by subaerial exposure during lowered sea level, the model depicts an arrangement of stratal geometries (onlap, downlap, toplap, backlap) that track the development of the sequence as it built firstly landward and then seaward during a relative sea-level cycle (Figures 1(a) and 2). Stratal geometries allow sequences to be subdivided into component packages of strata called 'systems tracts,' each associated with a segment of the controlling sea-level curve. Lowstand, transgressive, highstand, and shelf-margin systems tracts are recognized. Systems tracts are defined as a linkage of contemporaneous depositional systems, where a depositional system is in turn defined as a three-dimensional assemblage of lithofacies (Brown and Fisher, 1977; Van Wagoner et al., 1988). Thus, the SSM predicts a systematic distribution of environmentally controlled lithofacies (Figure 1(b)).

During the initial falling limb of the sea-level curve, the shoreline moves basinward toward and ultimately below the shelf edge. The former continental shelf is exposed to subaerial erosion, forming a lower bounding unconformity referred to as the sequence boundary (SB1). Subsequently, sediment is delivered to the slope where it onlaps the SB to form a basin-floor turbidite fan followed above by a wedge of terrestrial, shoreline, and shelf facies, the whole termed as a lowstand systems tract (LST). Subaerial exposure and consequent slow rates of lignite or soil formation at SBs are confirmed by their marked ¹⁰Be-isotope signature (Carter et al., 2002).

With rising sea level, the shoreline moves landward and inundates the lowstand coastal plain. Commonly, a transgressive surface of erosion (TSE; = ravinement surface, RS) is superimposed upon the former subaerial SB, accompanied by a shell lag containing reworked shoreface mollusks and remane fossils. Any fluvial channels that crossed the shelf to the former lowstand shoreline are delimited by the SB below, but have their LST fill beveled above by the TSE. Sediment bodies within such fluvial channels are referred to as incised valley fill. Deposition of a transgressive systems tract (TST) follows, with shallow marine sediments onlapping the TSE/SB in a landward

direction. Above the TSE and any shell lag, the vertical succession of lithofacies deepens upward from inner to offshore shelf facies. The distal TST tapers to a feather edge as the decreasing rate of terrigenous sediment supply causes stratal surfaces to converge seaward. The sediment-starved offshore shelf seafloor that results is marked in outcrop by a local flooding surface (LFS). ¹⁰Be-isotope studies show that the outcrop LFS corresponds with a significant hiatus (Graham et al., 1998), and the surface is often followed by a condensed, *in situ* shellbed with offshore fauna termed the mid-cycle shellbed (MCS) or “backlap” shellbed (Kidwell, 1991; Kondo et al., 1998). Such mid-cycle condensed successions are often associated with the presence of authigenic minerals such as glauconite and phosphate (Loutit et al., 1988).

As the rate of sea-level rise slows toward highstand and subsequent fall, clinoform strata advance basinward by offlap and downlap to form the highstand systems tract (HST). An abrupt boundary termed the downlap surface (DLS) occurs between the base of the HST and the underlying MCS or, in its absence, the top of the TST. The vertical succession of highstand facies shallows upward from offshore sediments at the base through shoreline and then into nonmarine facies at the top. As for the distal TST, distal highstand deposition is characterized by stratal convergence associated with low rates of terrigenous sediment supply.

At the approach of the next sea-level low, which ends each cycle, the shoreline and locus of deposition again shift basinward. Should the lowstand shoreline not fall below the shelf edge, Payton et al. (1977) distinguishes a SMST as forming at the start of the next new sequence, instead of a succeeding LST. As for the LST and HST, a SMST is characterized by an off-lapping, shallowing-upward facies succession.

Though it was part of the initial formulation of the SSM based on third-order cyclicity (Payton et al., 1977), the SMST has found little subsequent use. Rather, later authors have preferred to recognize two other types of regressive sediment bodies as characteristic of the falling sea-level phase. Regressive packages of strata form when the supply of sediment is large enough to form an offlapping body of sediment that builds into the basin as sea-level falls and the shoreline moves seaward (Plint, 1988), as is characteristic of Quaternary sequences from active-margin basins where high sediment fluxes are derived from nearby orogens. When they are bounded below by a regressive surface of erosion (RSE), generated by wave-base scour of the seafloor during regression, such deposits are assigned to a forced regressive systems tract (FRST) (Hart and Long, 1996; Hunt and Tucker, 1992). However, in many cases, similar sand-dominated regressive packages are gradationally based, presumably reflecting subsidence rates high enough to prevent a sea-level lowered wave base impinging on the seafloor. Such gradationally based sediment packages are common in the Wanganui Basin and are termed regressive systems tracts (RST) (Naish and Kamp (1997a). Sea-level lowstand is associated with the formation of the upper sequence-bounding unconformity (SB1).

Five Fundamental Sequence-Bounding and Intrasequence Surfaces

Following the theoretical analysis of Embry (1990), the study of Quaternary sequences has played a key role in developing our understanding of the outcrop characteristics of the

Figure 2 Quaternary sequence model based on outcrop studies of active-margin basins. (b) Quaternary sequence model emphasizing systems tracts, and the distribution of onlap and backlap shellbeds. (c) Indicative sequence motifs showing across-shelf variation in the vertical succession of facies, surfaces and systems tracts. Adapted from Naish TR and Kamp PJJ (1997) Sequence stratigraphy of sixth-order (41 ka) Pliocene-Pleistocene cyclothems, Wanganui Basin, New Zealand: A case for the regressive systems tract. *Geological Society of America Bulletin* 109(8): 978–999; Saul G, Naish T, Abbott ST, and Carter RM (1999) Sedimentary cyclicity in the marine Plio–Pleistocene: Sequence stratigraphic motifs characteristic of the last 2.5 my. *Geological Society of America Bulletin* 111: 524–537.

stratigraphic discontinuities that punctuate a typical stratigraphic sequence. However, note that a widely used term in older literature – the maximum flooding surface – is a conceptual horizon that has no necessary physical manifestation in outcrop (Carter et al., 1998). Recognition of the key physical surfaces, and the abrupt facies shifts that occur across them, are primary tools for sequence stratigraphic interpretation. The characteristics of sequence surfaces are summarized in Figure 2 and below.

Sequence Boundary

A SB is a surface formed by subaerial exposure that occupies a sequence-bounding position between an underlying RST, or HST, in the case where erosion has removed the RST and an overlying TST. The SB may be marked by incised fluvial channels, by a paleosol, or by terrestrial facies such as lignite, all of which formed during the sea-level lowstand associated with the formation of the SB. An SB-correlative conformity (conceptual horizon projected from the SB into adjacent conformable strata) may occur inland if aggradation of coastal plain facies

continues uninterrupted across the contact between two sequences. Offshore, an SB-correlative conformity extends basinward from beneath the LST.

Ravinement Surface or Transgressive Surface of Erosion

The RS and TSE are alternative, widely used synonyms for the surface that is wave-cut by the landward passage of a transgressing shoreface. The RS often erodes any underlying LST strata, its lower bounding SB and sometimes the upper part of the underlying sequence. The RS may be penetrated by marine crustacean burrows (*Thalassinoides*, *Ophiomorpha*) and pholad borings, and is often overlain by an onlapping shell lag or conglomerate.

Local Flooding Surface

The LFS marks the development of a sediment-starved seabed seaward of the shore-connected prism of the TST, and results from water deepening associated with shoreline transgression. The LFS is usually marked by a burrowed diastemic surface

between the top of the TST and an overlying MCS containing an *in situ* offshore shelf fauna.

Downlap Surface

The DLS is an abrupt but conformable boundary formed by downlap of the HST on to the underlying MCS or (in its absence) TST. The DLS may be burrowed and often coincides with a sharp lithological contrast between an underlying *in situ* shellbed and an overlying HST shelf siltstone.

Regressive Surface of Erosion

The RSE is a surface cut by a lowering wave base during regression and sea-level fall (Plint, 1988), and, where present, comprises the boundary between the HST and FRST. As for the DLS, a sharp lithological contrast may occur across the RSE in shelf settings, where it separates HST mudstone from FRST sand. In rapidly subsiding basins, where a balance exists between the rates of subsidence and sea-level fall, the HST passes gradationally upward into the RST without an intervening RSE.

Parasequences

In many depictions of the SSM, marine flooding surfaces correspond to the boundaries between high order, shallowing-upward, sedimentary cycles referred to as parasequences. These are regarded as the fundamental building blocks of sequences and systems tracts by Van Wagoner et al. (1988), who defined them as “a relatively conformable succession of genetically related beds . . . , bounded by flooding surfaces and their correlative surfaces.”

Depositional sequences are ultimately the product of the interplay between sedimentation, subsidence, and eustasy. Changes in the episodicity, magnitude, and rates of these fundamental parameters interact to vary the architecture and facies composition of depositional sequences according to the order of cyclicity and the particular basin setting. These considerations led Carter et al. (1991) to conclude that higher order sequences (e.g., parasequences) within lower order sequences are likely to be topologically distinct only at their particular level, rather than stacked as in a nested set of Russian dolls. These authors suggested that, rather than having a primary significance, parasequences are simply a convenient descriptive label, the scale of which varies according to sequence order.

Seven Empirical Orders of Sea-Level Cyclicity

Among the voluminous literature on sequence stratigraphy, examples exist of sequence architecture, which is interpreted in terms of about seven different orders of sea-level cyclicity (Fulthorpe, 1991). The first and second orders are ultimately tied to plate tectonic processes (Carter et al., 1991). Third- and fourth-order cycles are variously attributed to regional tectonic change (Saul et al., 1998) or to eustasy of unknown origin (Payton et al., 1977). The fifth, sixth, and seventh orders of sea-level cyclicity correspond to glacio-eustasy at orbitally forced Milankovitch scales (Miall, 1997).

The product of these various orders of sea-level variation can be integrated as a GSM (Haq et al., 1987), but such curves are bedeviled by their low resolution (sequences 1–10 My long) and uncertain accuracy. In reality, we only possess an acceptably accurate model of sea-level change for the last few million years, as underpinned by high resolution oxygen isotope time-series and related studies (Lisiecki and Raymo, 2005). It is the accuracy of the oceanic oxygen isotope sea-level curve as a proxy against which to assess stratigraphic change that makes studies of Quaternary sequence stratigraphy so exceptionally powerful.

Sequence Stratigraphy in Quaternary Sediments

Extending back to 2.6 Ma and beyond, orbitally forced glacio-eustasy has operated throughout the Quaternary with dominant frequencies of 20 ka (precession), 41 ka (obliquity), and 100 ka (eccentricity), and magnitudes between 70–130 m (see review by Pillans et al., 1998). Eustatic variation at these Milankovitch frequencies has driven numerous transgressions and regressions of the shorelines across the world's continental shelves, and imposed a distinct cyclicity on the Quaternary sedimentary successions that reside beneath modern continental shelves. A number of such basins located adjacent to active plate margins have been uplifted and exposed during the late Quaternary (Table 1), thereby allowing their detailed sequence stratigraphy to be described against the background of a known sea-level history. The discussion of Quaternary sequences below is based on the published literature on these active-margin successions.

Eustasy as the Dominant Control on Sediment Deposition

Tuning (or calibration) of the isotopic proxy sea-level curve with astronomically based master curves (e.g., seasonal insolation)

Table 1 Well documented outcropping Quaternary sequences from active-margin plate margins

has established that between 2.6 and 0.8 Ma, sea level varied systematically at the 41 ka obliquity wavelength, but that since 0.8 Ma, the 100 ka eccentricity signal has dominated. Magnitudes of Quaternary glacioeustasy can be calibrated between the oxygen isotope record and the sea-level changes inferred from uplifted coral terraces younger than the last interglacial (Chappell, 1974). This calibration has been used to estimate eustatic magnitudes of ~70 m for obliquity with cycles and up to 130 m for eccentricity cycles (Chappell et al., 1986). The oxygen isotope record from deep sea cores thus furnishes an independently established proxy eustatic curve against which to interpret Quaternary sequence stratigraphy.

Generally, rates of Quaternary glacio-eustasy outpace both subsidence and sediment supply as the dominant control on the sedimentary architecture of continental margin basins. Exceptions include the supply-driven Mississippi delta complex (Boyd et al., 1988) and the Canterbury Plains of New Zealand (Leckie, 1994), where different segments of the same coast in each case display concurrent offlapping and onlapping behavior during the Holocene highstand. However, more generally, the sequence architecture of some basin successions with good chronological control can be correlated to the oxygen isotope proxy sea-level curve. Following the conventional SSM, sediments deposited across a Quaternary highstand shelf can be matched to interglacial sea-level highs, while their contained sequence boundaries correspond to the intervening glacial lowstands (Abbott and Carter, 1994; Ito, 1992; Pillans et al., 1994, 2005).

Sedimentary Facies Analysis

The architecture and depositional history of sequences are rendered using standard sedimentary facies analysis. This approach uses sediment attributes such as grain size, physical sedimentary structures, biogenic sedimentary structures, and macrofossil content to interpret environments of deposition (Walker, 1984). Lithofacies analysis is enhanced by identification of the significant surfaces that punctuate sequence successions and by focused sedimentological and paleoecological analysis. The taxonomic composition of macrofossil assemblages is indicative of environmentally diagnostic paleocommunities (Abbott and Carter, 1997; Kidwell, 1991; Kondo et al., 1998). Thus, estuarine faunas are distinct from open shoreface faunas, and both are distinct from offshore subtidal communities. Taphonomic attributes of macrofossil material indicate sedimentary processes (Kidwell, 1991b). For example, broken and abraded assemblages indicate reworking in an energetic environment (death assemblages), whereas pristine assemblages characterized by the presence of paired valves (life assemblages) indicate deposition in low energy settings. Foraminiferal paleoecology is also a powerful tool with which to interpret facies and track bathymetric changes in Quaternary marine strata (Abbott, 1997; Haywick and Henderson, 1992; Naish and Kamp, 1997b). Overall, analysis of the sedimentology and paleoecology of Quaternary sedimentary successions is highly robust because close contemporary analogues often occur in adjacent modern sedimentary environments.

The distribution of facies within a sequence is the basis from which stratal geometries and sequence architecture can

be inferred. For example, a deepening-upward facies succession that fines upward from physically stratified shoreline sand into pervasively bioturbated shelf mud, has inferred onlapping stratal geometry such as characterizes the TST. Conversely, a shallowing- and coarsening-upward succession represents offlapping geometry such as that found in the HST–RST. Thus a conformable succession of gradually changing facies may often correspond to a systems tract (Walker, 1990).

The Importance of Shellbeds

Shell-rich facies are a hallmark of eustatically influenced Quaternary sequences and their interpretation is crucially important for resolving sequence architecture. Shell material becomes concentrated under conditions of low net terrigenous sediment accumulation created by either reworking and bypass in shallow energetic sandy environments (type A shellbeds; Abbott and Carter, 1994), nondeposition in nearshore deeper channel or offshore deeper water muddy environments (type B shellbeds, *op. cit.*), or by infaunal penetration of specialist boring taxa into a current-swept, hard substrate (type C shellbeds, *op. cit.*).

All such shelly deposits represent stratigraphic condensation, and type A and B shellbeds both imply convergence of stratal surfaces toward sequence and systems tract bounding surfaces (Kidwell, 1991a; Kondo et al., 1998; Naish and Kamp, 1997a). Individual shellbeds can be assigned an inferred mode of origin with respect to sequence architecture (Figures 2 and 3), as follows. Basal onlap shellbeds represent transgressive reworking of contemporaneous shelly shoreline and estuarine sediments at TSE, with an admixture of underlying remanie fossils. Fossil content comprises mostly mixed, rounded, and transported assemblages dominated by sandy shoreface and estuarine mollusks. Inferred backlap shellbeds correspond to MCS, and are characterized by offshore shelf faunas, which include *in situ* articulated bivalves. Downlap shellbeds that mark the contact of MCS and HST are characterized by similar offshore shelf faunas but display a more dispersed biofabric than do the immediately underlying backlap shellbeds. Finally, inferred toplap shellbeds occur within the upper parts of RST or FRST, where stratal convergence results from sand bypass in high-energy shoreface environments. Skeletal material is preserved in the sediments in which the organisms lived, and though assemblages are reworked, disarticulated, and fragmented, they are neither significantly rounded nor display the other typical lag features that characterize basal onlap shellbeds. In some sequences, onlap and backlap shellbeds are superimposed to form a compound shellbed.

Quaternary Sequences

How Are They Special?

It is a prime feature of Quaternary sediments from active-margin basins that they exhibit a much greater resolution of sequence architecture than that depicted by the generic third-order SSM. For example:

1. Figure 2 depicts an SSM for the Quaternary, based mainly on outcrop studies of uplifted basins adjacent to active plate margins; and

Figure 3 The association between shellbed type and sequence architecture in Plio-Pleistocene sequences. Reproduced from Kondo Y, et al. (1998) *The relationship between shellbed type and sequence architecture: Examples from Japan and New Zealand. Sedimentary Geology* 122: 109–127.

(a) Distribution of shellbed types within an idealized sequence, showing their relationship to stratal convergence and systems tract-bounding surfaces.

(b) Vertical facies succession within a sequence showing the stratigraphic context of shellbed types.

2. **Figure 4** is an example of a measured section from the Canoa Basin, Ecuador, labeled to show the component facies, sequences, systems tracts, and surfaces.

A second important feature of Quaternary sequences is that subaerial sequence boundaries are not usually preserved but are instead superposed by the TSE cut by the passage of a transgressing marine shoreface. A TSE may cause erosion of up to several tens of meters into the top of the underlying sequence, which removes all traces of original sequence boundaries almost basin wide (Abbott, 1992; Abbott and

Carter, 1994) and results in the preservation of top-truncated sequences (Castlecliff motif of Saul et al., 1998). Deep erosion during transgression also leads Quaternary sequences deposited in inner-shelf and basin margin settings to possess proportionally thick TSTs.

A third difference between the Quaternary SSM and the generic third-order SSM is the common presence of strata deposited during the falling limb of the relative sea-level curve. Regressive packages of strata deposited during falling sea level form when the supply of sediment is large enough

Figure 4 Vertical succession of facies (including shellbeds), sequences, and systems tracts within the Canoa formation, Canoa Basin, central Ecuador. Reproduced from Di Celma C, Ragaini L, Cantalamessa G, and Landini W (2005) Basin physiography and tectonic influence on sequence architecture and stacking pattern: Pleistocene succession of the Canoa Basin (central Ecuador). *Geological Society of America Bulletin* 117: 1226–1241.

to form an offlapping body of sediment that builds into the basin as the shoreline regresses. As described earlier, such sediment bodies are either bounded below by an RSE and termed FRST, or else grade up from underlying HST sediments to comprise a simple RST.

Fourth, very high sedimentation rates and rapid shellbed formation accompanied active-margin basin-filling during Quaternary eustatic cycles. Individual 40 ka-long late Pliocene sequences attain 120 m or more in thickness, with HST–RST alone over 100 m thick (Haywick et al., 1992; Naish and Kamp, 1997a) (Figure 5). Therefore, average sedimentation rates at times reached 5 m ka^{-1} or more, and MCS up to $\sim 1 \text{ m}$ in thickness, despite being ‘condensed’ with respect to their enclosing TST–HST sediment, nonetheless took only a few thousand years to accumulate (Abbott and Carter, 1994).

Finally, and fifth, it is only in Quaternary successions that the complete three-dimensional architecture of continental margin sequences can be studied within a known sea-level context. Outcrop studies can be accomplished not only on uplifted Plio-Pleistocene shelf (Abbott and Carter, 1994) and slope (Ito, 1992) successions, but also on the important shore-face-coastal cliff-coastal plain interface that is preserved in the treads of flights of uplifted marine terraces back to mid-Pleistocene in age (Chappell, 1974; Pillans, 1983).

Sequence Motifs

The vertical stratigraphic succession of facies, faunas, and surfaces within a sequence varies according to its location along a hypothetical shore-normal profile. Particular types of stratigraphic succession can be differentiated as sequence motifs. As discussed by Saul et al. (1999), sequence motifs are arbitrary end-members in a continuous spectrum of possible sequence architectures. Furthermore, the interplay of subsidence and sediment supply, and therefore shore-normal variation in sequence motifs, varies in detail both within and between basins. The generic motifs depicted in Figure 2(c) are drawn from earlier studies of geographically named motifs, generalized here in order to illustrate typical cross-basin variation in Quaternary sequence architecture and facies composition (Figure 6).

Basin margin motif

The edges of active-margin basins often record a history of progressive Quaternary uplift. Wave-cut terraces are formed at interglacial highstands, and flights of terraces formed at successive highstands extend from the modern highstand shoreline into the uplifting hinterland (Pillans, 1983). Terrace treads comprise sediments that represent the landward margins

Figure 5 Photo of outcrop exposure of Early Quaternary (2.5–2.0 Ma), 40-ka-duration, shallow-marine sequences exposed in cliffs of the Rangitikei Valley, Wanganui Basin. Sequence boundaries (TSEs) are marked by red dashed line. Individual 40-ka sequences are up to 45 m thick. The stratigraphic column shows these sequences correlated with deep sea oxygen isotope record. Modified from Naish TR and Kamp PJJ (1997) Sequence stratigraphy of sixth-order (41 ka) Pliocene–Pleistocene cyclothem, Wanganui Basin, New Zealand: A case for the regressive systems tract. *Geological Society of America Bulletin* 109(8): 978–999.

of depositional sequences, and sequences formed in this paleogeographic setting are intimately related to the geomorphic expression of the terraces (see [Morphostratigraphy/Allostratigraphy](#)).

For most of the sea-level cycle, the basin margin is subaerially exposed. Sedimentation in this setting consists of nonmarine facies, including substantial paleosol development, together with shallow marine facies deposited at and near each interglacial sea-level peak. The sediments can be partitioned into

transgressive and HSTs. In this setting, sequence-bounding RS may terminate at paleocliffs that represent the position of the highstand paleoshoreline.

Inner-shelf sequence motif

The inner-shelf setting is inundated from mid- to late-rise through to highstand. In contrast to the basin margin motif, paleodepths in this setting may reach several tens of meters, so a proportion of sequences in this paleogeographic setting

Figure 6 (a) Conceptual sequence stratigraphic and (b) chronostratigraphic models for orbital scale Quaternary sequences based on Wanganui Basin. The stratigraphic architecture timing of development of systems tracts and key surfaces are shown with respect to a relative cycle of sea level. Outcrop motifs of Wanganui sequences are illustrated in the context of a 2D coastal plain and outer shelf progradational setting. Reproduced from [Naish T, Field B, Zhu H, et al. \(2005\)](#) Integrated outcrop, drill core, borehole and seismic stratigraphic architecture of a cyclothemic, shallow-marine depositional system, Wanganui Basin, New Zealand, *Journal of the Royal Society of New Zealand* 35: 91–122.

consists of facies deposited at shelf depths. Thick TSTs begin with an onlap shellbed that deepens upward. Because this motif is proximal to the basin margin, transgressive sedimentation switches rapidly to highstand deposition as relative sea level approaches its peak. Therefore, backlap shellbeds may not be well developed at the transgressive-HST boundary. Highstand deposits are mud-rich, but may become sand-rich toward the top. During the ensuing sea-level fall, there is an accompanying abrupt basinward shift in deposition and wave base is lowered to the point where it scours the shelf. This basinward passage of wave base may generate a RSE, over which lies a body of shoreface sand assigned to the forced RST. As for the basin margin, the inner-shelf paleogeographic position may also be affected by tectonic uplift. Thus, inner-shelf sequences from the Peradriatic basin (Cantalamesa and Di Celma, 2004) are stacked in a basinward stepwise manner, describing a low-order tectonically forced regression.

Mid-shelf sequence motif

As for the proximal motifs, sequences in the mid-shelf paleogeographic position also commence with a relatively thick TST with a basal onlap shellbed. In contrast to the inner-shelf motif, the uppermost TST in the mid-shelf position is more likely to be isolated from terrigenous sediment, and the time until downlap by the highstand is likely to be greater. Thus, here and also in the more distal motifs, shell material accumulates *in situ* to form well-developed backlap shellbeds.

Highstand deposition on the mid-shelf is heralded by downlapping shelf mud that 'quenches' shell accumulation, resulting in an abrupt yet conformable DLS between shell-rich and relatively shell-poor facies. Shelly clumps and bands at the base of some highstand successions represent downlap shellbeds, but these are not as well developed as the underlying backlap shellbeds. As for the inner-shelf motif, highstand shelf mud passes into shoreline sand deposited during falling sea level. However, on the mid-shelf, the rate of subsidence is higher, so wave base is not lowered to the extent where it cuts a RSE. Instead, the transition is conformable and the overlying sands are attributed to the RST rather than the forced RST.

Outer-shelf sequence motif

This sequence motif results from deposition on the outer shelf, between early relative sea-level rise through to the late part of sea-level fall. The outer-shelf motif is highly asymmetrical in the sense that sand-rich transgressive facies are not well developed compared to the thick, sand-rich RST. The poor development of the TST may result from rapid transgression over a low gradient coastal plain, which then becomes isolated from the supply of terrigenous sediment. The resulting TSTs are thin and particularly rich in skeletal material. The basal onlap shellbed may be directly overlain by a backlap shellbed to form a compound shellbed. As for the mid-shelf motif, the DLS forming the boundary between the transgressive and HSTs is an abrupt shell-rich to relatively shell-poor boundary. The upper part of the motif is a gradationally based RST of shoreline sand.

Slope sequence motif

Quaternary sequences of this motif are less well known from outcrop, so this motif is based on the Plio-Pleistocene of the Hawke's Bay basin described by Haywick et al. (1992). This setting lies basinward of the lowstand shoreline, so is

inundated through the entire relative sea-level cycle. Erosional sequence-bounding surfaces associated with subaerial exposure or marine ravinement are often not present. Instead, sequences in this paleogeographic position are bounded by correlative conformities. Another feature of this motif is that it comprises exclusively offshore facies because the slope paleogeographic setting is submerged to depths of over 100 m during most of the relative sea-level cycle. Only the basinward-tapering edges of the transgressive and HSTs are represented and, because of the pronounced convergence of stratal surfaces in the distal TST, backlap shellbeds may be well developed. Facies successions shallow upward as the regressing shoreline reaches lowstand. In the case of the Hawke's Bay basin, this coincided with a reorganization of terrigenous sediment transport paths, such that LSTs comprise coquina limestone.

Case Study 1: Characterizing, 5th- and 6th-Order Quaternary Shallow-Marine Sequences from Outcrop, Borehole, Drillcore, And Seismic Data from Wanganui Basin, New Zealand

Continental margins are relatively rare that afford an opportunity to study the stratigraphic architecture of shallow-marine depositional systems on spatial scales ranging from core and borehole (millimetres/centimetres) to outcrop and seismic (tens of meters), during periods of known sea-level oscillations. Wanganui Basin, New Zealand is one of a small number of Pliocene-Pleistocene basins worldwide (Browne & Naish 2003; Kitamura et al., 2000) in which sedimentation evidently kept pace with subsidence through much of the basin history, resulting in a 5-km-thick record of predominantly shelf and shallow-water sediment. Gentle upwarping of the eastern margin of the basin has produced spectacular exposures, along coastal cliffs and inland (Figure 5) within the heavily dissected and uplifted landscape, through as many as 44 depositional sequences deposited during the last 2.5 Ma (Carter & Naish, 1998; Naish et al., 1998; Saul et al., 1999).

The Wanganui stratigraphic succession comprises a range of siliciclastic and carbonate sediments deposited in shelf, shoreline, and coastal plain depositional environments during orbitally controlled sea-level fluctuations of 41 ka- and 100 ka-duration. Over the last 10 years, this margin has gained a reputation as one of the world's outstanding outcrop examples of a Pliocene-Pleistocene shallow-marine, clastic depositional system (e.g., summary papers: Abbott and Carter 1994, Abbott 1997; Naish & Kamp 1997a; Naish et al., 1998; Saul et al., 1999). Outcrop analogues of this quality are rare, as most Quaternary shelf margins underlie flooded continental shelves (e.g., Gulf of Mexico).

Late Pliocene to mid-Pleistocene (ca. 2.1–0.4 Ma) strata exposed in the coastal cliff sections northwest of Wanganui City, North Island New Zealand, comprise 25, 6th(41 ka)- and 5th(100 ka)-order, shallow-marine to marginal marine stratigraphic sequences, deposited during global glacio-eustatic sea-level cycles corresponding to Marine Isotope Stages (MIS) 78–10. Naish et al. (2005) characterized the sequences using: (1) a series of drill cores sited above and behind the coastal outcrops, which recovered a composite record of ca. 450 m, (2) a new high-resolution multichannel seismic reflection profile acquired along the beach adjacent to the coastal cliffs, and (3) downhole digital logs from the boreholes (Figures 7 and 8). They integrated the outcrop and subsurface data sets to

Figure 7 Summary composite log of the Castlecliff-1/1A drillcore, Wanganui Basin, and borehole shows neutron porosity (NPHI), density (RH08), and natural gamma (EHGR) borehole electric logs, synthetic seismic well-tie, lithologic log, sequence stratigraphic interpretation, oxygen isotope stages, lithostratigraphy, and environmental and paleobathymetric interpretations. Reproduced from Naish T, Field B, Zhu H, et al. (2005) Integrated outcrop, drill core, borehole and seismic stratigraphic architecture of a cyclothem, shallow-marine depositional system, Wanganui Basin, New Zealand, *Journal of the Royal Society of New Zealand* 35: 91–122.

Figure 8 Pleistocene, shallow marine sequences exposed in the coastal Castlecliff section, Wanganui Basin, New Zealand are correlated with drill core logs from ‘behind-outcrop’ boreholes and high-resolution seismic data from along the beach at the base of the coastal cliffs (after Naish et al. (2005); reproduced from Graham (2008)).

produce a high-resolution model of the stratigraphic signatures and 2-D architecture of a cyclical, shallow-marine depositional system.

Case Study 2: Outcrop Examples of Orbitally Influenced Pleistocene Shelf Sequences Preserving Forced Regressive Deposits, Croton Basin, Southern Italy

On a global scale, the Croton Basin preserves one of the best-developed and most complete Pleistocene marine records available in outcrop, as important as those in California, New Zealand, and Japan. The preservation of high-resolution Quaternary sequences occurred through the interaction between high-amplitude global sea-level fluctuations within an extension rift basin. The 550 m-thick composite succession contains 13 orbital-scale sedimentary cycles correlated with Marine Isotope Stages 33 to 7 during a long-term shallowing from upper slope-outer shelf to marginal marine-coastal plan environments between ~1.2–0.25 Ma (Massari et al., 2002). An unconformity of tectonic origin, which is marked by an abrupt shallowing and the first evidence of fluvial incision, punctuates the succession at the base of Sequence 9 removing the record corresponding to MIS 16–12 (~0.65–0.45 Ma) (Figure 9). Correlation of the sedimentary cycles with the deep-sea oxygen isotope record is constrained by an integrated, tephro-, bio-, magneto stratigraphy (Rio et al., 1996; Massari et al., 2002). The cyclothemic nature of the record is characterized by a stack of simple or composite, seaward-prograding, sand-dominated tongues deposited during regressions and intervening aggradational mud-dominated deposits related to transgressive-deepening and highstand episodes. High rates of basal subsidence and high rates of sediment supply have allowed exceptional outcrop examples of forced regressive systems tracts to be preserved in some sequences (Massari et al., 1999) (Figure 10).

Astronomical Calibration

Calibration of orbitally forced oxygen isotope records from the deep sea with astronomical solutions for orbital precession, obliquity, and eccentricity have led to the development of an oxygen isotope numerical timescale extending back to the late Miocene (Lourens et al., 1996; Shackleton et al., 1990). Peaks and troughs in oxygen isotope records are consecutively numbered as isotope stages. For Quaternary shelf successions, the preserved sequences generally correspond to interglacial (odd-numbered) stages, while sequence-bounding unconformities correspond to glacial (even-numbered) stages.

Extended Quaternary successions in the Boso Peninsula, Japan, and the Wanganui Basin, New Zealand, have been correlated in detail with the sea-level history contained in the oceanic oxygen isotope scale. For example, Naish et al. (1999) and Pillans et al. (2005) used geomagnetic reversals and numerous dated tephra horizons to calibrate 43 Wanganui sequences with oxygen isotope stages 1–100 (Figure 11), and Pickering et al. (1999) correlated Boso sequences with isotope stages 15–35. Apart from their intrinsic interest, such calibrations enable absolute dates to be estimated for the boundaries of local Stages, for biostratigraphic events such as first and last appearances, and for many otherwise undated stratigraphic units (cf. Carter 2005).

Summary

1. Glacioeustasy driven by orbital precession (20 ka), obliquity (41 ka), and eccentricity (100 ka) has imposed sedimentary cyclicity on the fill of Quaternary continental margin basins. Such cycles are represented as fifth- to seventh-order sequences by sediments within recently uplifted active-margin basins, each sequence being attributable to deposition during one cycle of sea-level change.

Figure 9 Correlation of the Pleistocene San Mauro shallow-marine cyclothem succession, Croton Basin, with the marine oxygen isotope stratigraphy. Reproduced from [Massari F, Rio D, Sagveti M, et al. \(2002\)](#) Interplay between tectonics and glacio-eustasy: Pleistocene succession of the Croton basin, Calabria (southern Italy). *GSA Bulletin* 114: 1183–1209.

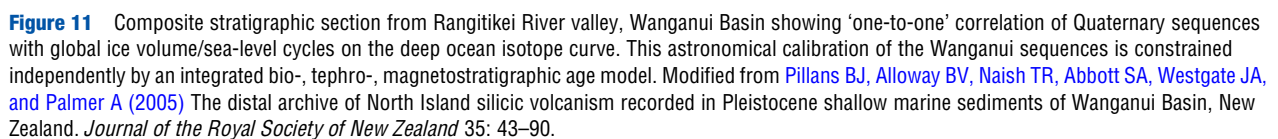

Figure 10 (a) Schematic, dip-oriented cross-section linking cyclothem sections within the Croton Basin shows the 2-D sequence stratigraphic architecture of orbitally influenced Pleistocene shallow-marine sequences. Note the preservation of thick, seaward prograding, shore-connected sediment wedges interpreted as forced regressive deposits. (b) A more detailed example of the sequence architecture of Croton Basin sequences showing the downward shift of facies during forced regression, marked by an RSE or DWS (downward shift surface) beneath the FRST.

- Analysis of sedimentary sequences is undertaken using standard sedimentary facies analysis, supported by paleoecological and taphonomic analysis of fossil faunas. Stratal architecture within sequences is inferred from the succession of facies (grouped as systems tracts) and stratigraphic surfaces that occur within a sequence in the following invariant order: lower SB, LST, TSE, TST, LFS, MCS, DLS, HST, regressive or forced RST, and upper SB.
- The vertical representation of facies and systems tracts within a Quaternary sequence varies along a hypothetical cross-shelf profile. Five sequence motifs are recognized, which characterize the spectrum of sedimentary variation that exists between the inner basin margin and the offshore basin slope.
- Calibration of lengthy Quaternary sequence successions from Japan (Boso Peninsula) and New Zealand (Wanganui Basin) with the orbitally tuned oxygen isotope timescale has been achieved using geomagnetic reversals and dated tephra. Sequences deposited in shelf settings correspond to odd-numbered (interglacial) stages on the oxygen isotope timescale, while the even-numbered (glacial) stages are represented by sequence-bounding unconformities. Such calibration allows numerical ages to be assigned to otherwise undated stratigraphic entities such as local lithostratigraphic units, relative time scales, and fossil first and last appearances.
- Studies of Quaternary sequence stratigraphy have demonstrated:
 - a much greater resolution of sequence architecture than is depicted by generic sequence stratigraphic models;
 - that subaerial sequence boundaries are rarely preserved intact, but instead are superposed by a TSE cut by shoreline passage during the rising sea-level stage of the next eustatic cycle;
 - the common preservation of thick, sandy RST strata during the falling stage of a eustatic cycle;
 - the occurrence of highstand and RST sedimentation rates as high as 5 m/ka, and the formation of shellbeds in as little as a few ka, in sequences from uplifted active-margin basins; and
 - the availability for study of the three-dimensional architecture of complete continental margin sequences in the light of the independent proxy sea-level history that is represented by the oceanic oxygen isotope record.

Glossary

Tephra: This word originates from the Greek word *tephra* (τεφρα) meaning 'ashes.' It is an all-embracing term for the explosively erupted, loose fragmental (pyroclastic) products of a volcanic eruption, and includes all grain sizes ranging from fine dust to large blocks that may be several meters across. The plural is either tephra or tephra. (Strictly, 'tephra' is feminine singular and hence in Greek is used as a collective noun with singular verb forms, but appending 's' is quite appropriate in modern usage.) Tephra may include fall deposits (commonly called tephra fall or tephra fallout) and unconsolidated deposits derived from pyroclastic density currents (surges, flows, and transitional gas-water supported flow deposits). The term 'airfall' is no longer used.

Tephrochronology: The use of tephra as isochrons (time-parallel marker beds) to link sequences in different places via precise tie-points and to establish relative or numerical ages.

Tephrostratigraphy: Refers to the study of sequences of tephra layers or strata and associated deposits and their distribution, and their relative and numerical ages. It involves defining, describing, and characterizing or 'fingerprinting' tephra or tephra sequences using their physical, mineralogical, or geochemical properties, and underpins tephrochronology.

Cryptotephra: Refers to distal tephra deposits, preserved as glass shard and/or crystal concentrations in peat bogs, lake, marine, or aeolian sediments, or ice-cores, or soils, that are essentially not visible as a layer in the field. The term and its derivatives (cryptotephrostratigraphy, cryptotephrochronology) originate from the Greek *kryptein*, to hide, to convey the hidden or concealed nature of these typically fine-grained, sparse deposits.

Tephrochronometry: Refers to obtaining a numerical age or date for a tephra layer or cryptotephra.

Introduction

The word 'tephra' originates from a Greek word *tephra* (τεφρα) meaning 'ashes.' It is an all-embracing term for the explosively erupted, loose fragmental (pyroclastic) products of a volcanic eruption, and includes all grain sizes ranging from the finest dust to blocks the size of cars. The plural is either tephra or tephra – the former (as a singular collective noun) is more technically correct but the latter avoids ambiguity and is in common usage. Tephra may include fall deposits (commonly called tephra fall or tephra fallout) and unconsolidated deposits derived from pyroclastic flows or surges. Related terms include tephrostratigraphy, tephrochronology, and tephrochronometry. Note that in these derivatives the letter 'o' rather than 'a' is the appropriate connecting letter. The first known written use of 'tephra' was by Aristotle who described an eruption on the island of Hieria in the Lipari (Aeolian) Islands near Sicily around 350 BC. The first modern usage was by Sigurdur Thorarinsson of Iceland in 1944, who resurrected the term to fit with Greek words lava and magma and to link these with classical volcanology that derives from the Roman name for the island Vulcano, the southernmost of the Lipari Islands.

Tephra deposits have two special features: (1) they are erupted and deposited over very short time periods, geologically speaking, usually a matter of only hours or days to

perhaps weeks or months and (2) they can be spread widely over land and sea to form a thin blanket that (unless reworked) has the same age wherever it occurs. Therefore, once it is identified by its mineralogical and geochemical properties, a tephra layer provides a time-parallel marker bed or isochron for an 'instant' in time, that instant being the date of the eruption that produced the layer. 'Tephrochronology' is thus the use of tephra deposits as isochrons to link sequences in different settings via precise tie-points and to establish and transfer relative or numerical ages (Lowe and Hunt, 2001). In recent times, the term 'tephrochronology' has tended to be used in a broader way as a stand-alone term for all aspects of tephra studies (e.g., Lowe, 2011; Shane, 2000).

'Tephrostratigraphy' is another term that is commonly used and refers to the study of sequences of tephra layers and related deposits and their relative and numerical ages. It involves defining, describing, mapping, and characterizing or 'fingerprinting' tephra or tephra sequences using their physical, mineralogical, or geochemical properties, and fundamentally underpins tephrochronology. Several lines of evidence are needed to ensure confidence in most tephra correlations: (1) stratigraphic position, which provides relative age; (2) intrinsic compositional properties that are diagnostic and persistent; and (3) numerical age, normally based on radiometric, incremental, or other dating techniques.

Early Studies: Pioneers of Tephrochronology

Studies of tephra layers as a tool for research in various disciplines effectively began in the 1920s and 1930s in New Zealand, Japan, Iceland, South America, and USA. In New Zealand and Japan, pioneer tephra studies were carried out in association with soil surveys (Grange, 1931; Uragami et al., 1933). Sigurdur Thorarinsson, an Icelandic volcanologist, is widely regarded as the modern 'father of tephrochronology' (Figure 1). He worked with founder palynologist Lennart von Post in Sweden at the University of Stockholm from 1932 and realized that the numerous Icelandic tephra layers offered great possibilities for correlation and dating. A few years earlier, two Finnish geologists V. Auer and Th. G. Sahlstein had used tephra layers as marker horizons in their studies of vegetation history of Tierra del Fuego. Together with Hakon Bjarnason, Thorarinsson began work on the identification and mapping of some widespread tephra layers (Bjarnason and Thorarinsson, 1940) to obtain dated horizons in Icelandic bogs as an aid to studies of vegetation changes and rates of soil formation and soil erosion. Later, Thorarinsson (1944) published his doctoral thesis (in Swedish) in which he defined the terms 'tephra' and 'tephrochronology.' His immense contributions to the discipline are summarized in two of his last papers prepared for an international tephra meeting held in Iceland in 1980 (Thorarinsson, 1981a,b).

Characteristics of Tephra

Magnitude and Dispersal

Tephra layers are derived from explosive eruptions that inject particles (pyroclasts) to tropospheric and even stratospheric levels. The particles are carried upward by an eruption column that consists of a lower gas-thrust region and an upper convective region. A column will continue to rise convectively until its density is equal to that of the surrounding atmosphere. It will then expand laterally but will also continue upward due to its momentum to form a broad umbrella cloud that plays an important role in the transport of pyroclasts. Temperature of the erupted material and mass eruption rate determines the height of an eruption column which, along with particle size, wind strength, and direction, exerts the principal controls on the long-distance transport of tephra. Three dominant threshold settling velocity values affect the distribution and sorting of airborne tephra: (1) fragments with large settling velocities follow ballistic trajectories that are little affected by wind and only slightly by the expanding eruption cloud, (2) particles suspended by turbulence in the eruption cloud that are too heavy to be suspended by atmospheric winds, and (3) those light enough to be suspended by wind independently of the eruption cloud. Wind may modify the trajectories of all but the largest fragments; fragments held in turbulent suspension within the eruption cloud begin to fall according to their settling velocities as the energy within the cloud dissipates (Figure 2).

Tephra particles range in size from ash (<2 mm) and lapilli (2–64 mm) to blocks (dense, angular) and bombs (vesicular, rounded) (>64 mm) that may reach several meters in diameter. Densities vary from low density, vesicular pumice, and scoria to dense crystals and rock fragments. Materials may be juvenile (formed from magma involved in the eruption) or accidental or xenolithic (derived from preexisting rock or from material beneath the volcano, respectively). Silicic tephra are typically much more widely dispersed than those of basaltic composition.

Tephra are distributed in two-end member patterns with many variations: circular patterns from low-eruption columns during calm conditions (Figure 3(a)) and elliptical to fan-shaped patterns from high-eruption columns that encounter strong unidirectional winds (Figure 3(b)). The most typical pattern is fan shaped with the apex at or near the source with multicomponent sheets radiating out from a common source or overlapping with slightly different distribution trends depending on shifting wind directions. Tephra blankets tend to be gentle wedges that systematically thin along an axis away from source and are best defined by an isopach map constructed from numerous thickness measurements. The layers decrease exponentially in thickness and grain size with increasing distance from source, a reflection of sorting of particles by size and density as they fall through the atmosphere. In some historical eruptions (e.g., Mt. St. Helens, 1980), isolated areas of increased thickness are present in the distal portions of tephra plumes. Several tephra transport models have been developed which relate distance from source to grain size for volcanic eruptions of varying intensity and for varying atmospheric wind profiles and seasonality. Unusually, powerful eruptions give rise to tephra layers easily recognizable

Figure 2 (a) Tephra plume of the 1996 eruption of Ruapehu volcano. Photograph courtesy of Vern Manville, University of Leeds. (b) Eruption plume of Ruapehu volcano, central North Island, New Zealand, as seen from space in 1995. Photograph courtesy of Landcare Research, New Zealand.

1000 km or more from source (Figure 4(a) and 4(b)). The fine ash can be carried over areas of continental size or larger and extend far beyond the recognizable limits of the dispersal fan.

The initial eruption of the Icelandic Eyjafjöll volcano during the Northern Hemispheric spring of 2010 has shown that it is not the most voluminous of eruptions that necessarily result in the widest dispersal of tephra. The AD 2010 Eyjafjöll eruption was relatively small scale (>0.01 to <1 km³) when compared to the super-eruptions of Youngest Toba (ca. 74 ka before present (BP); Figure 4(a)) or Lava Creek B (ca. 0.64 Ma; Figure 4(b)), both of which have explosivity indices at the highest end of the scale (VEI 7–8) with erupted volumes in excess of >100 km³. Yet, this relatively low-magnitude event upwind of mainland Europe and the prevailing wind direction led to widespread and unprecedented disruption to air travel over Europe with significant economic consequences. Following the onset of the eruption, satellite imagery demonstrated the rapid transportation of ash by westerly winds over mainland Europe, eventually expanding to large areas of the North Atlantic Ocean extending toward the eastern seaboard of Canada (UK Met Office, 2010). The AD 2010 Eyjafjöll event

highlights that weather patterns at the time of eruption can not only play a critical role in the transportation and deposition of a relatively small amount of tephra, but also serves as a clear reminder of the unexpected and costly impacts of ash inundation in distal areas downwind of volcanic sources (Davies et al., 2010).

Sparse glass shards from widely dispersed tephra occasionally occur within acid layers preserved in high-latitude ice cores, and geochemical analysis of these can be used to link to other records or to refine calendrical age. For example, the Icelandic-sourced Vatnaöldur tephra layer, deposition of which coincided with the Norse settlement at ca. 874, has Greenland ice-core dates of AD 871 ± 2 and 877 ± 7 (Grönvold et al., 1995; Zielinski et al., 1997). The powerful Mazama eruption in Oregon, USA, has an ice-core age of 7627 ± 150 calendar year BP (Zdanowicz et al., 1999; Figure 5). The ice-core derived calendar ages improve the possibility for correlation of paleoclimate records developed from terrestrial and lacustrine sediments in areas where these tephtras are known. Such records are now able to be better linked to ice-core and marine records via tephrochronology (e.g., Davies et al., 2007, 2008).

Field Characteristics

Macroscopic

Tephtras, depending on the distance from source, can range from millimeter- to meter-thickness, typically mantle preexisting topography (Figure 6) and often display marked lateral variations in thickness and continuity. In general, bedding in near-source (proximal) tephra deposits consists of alternating gradational coarse- to finer-grained layers without sharp bedding, but whether bedding is sharp or gradational depends upon several factors such as the duration and energy fluctuations of an eruption, tephra volume and discharge rate, direction and strength of winds during the eruption, and the duration between eruptions during which erosion, weathering, or winnowing of fines from the tephra may take place. Where the upper part of a tephra layer (in terrestrial settings) is weathered and modified by soil-forming processes, it becomes a paleosol upon burial by subsequent deposits (Figure 7).

Thin (centimeter-thick), distal tephra layers transported by winds over long distances are commonly massive to normal graded (Figure 8) and may be affected by bioturbation, soft-sediment deformation and locally reworked material washing into the site. Lower contacts are generally sharp and planar, whereas the upper contacts can be gradational admixtures of nonvolcanic grains over millimeters to meters up section. Some tephra layers can display tractional sedimentary structures such as trough cross-stratification from reworking in shallow marine and fluvial aqueous environments (Figure 9).

Difficulties can arise relating to the preservation of millimeter-thick distal tephra in marine and other sediments. Although such tephtras may occur as a single, thin continuous horizon, in many cases glass shard concentrations may be discontinuous and dispersed through a band of sediment up to several decimeters in thickness. This dispersal presents the problem of determining which stratigraphic position

Figure 3 Tephra distribution patterns. (a) Tephra distribution patterns. Circular isopach map of Algar do Carrao I scoria-fall deposit associated with a low-intensity basaltic eruption at Tereira, Azores (reproduced from Self S (1976) The recent volcanology of Terceira, Azores. *Journal of the Geological Society of London* 132: 645–666), and (b) elliptical pattern associated with tephra fallout from the Mt. St. Helens eruption, 1980, that spread as far as 1000 km from the volcanic center in less than 10 h (reproduced from Sarna-Wojcicki AM, Shipley S, Waitt RB Jr, Dzuris D, and Wood SH (1981) Areal distribution, thickness, mass, volume, and grain size of air-fall ash from six major eruptions of 1980. In: Lipman PW and Mullineaux DR (eds.). *The 1980 Eruptions of Mount St. Helens*, pp. 577–600. Washington: US Geological Survey Professional Paper 1250).

represents the point of actual tephra deposition. Usually, the point of maximum shard concentration in a section or core is regarded as marking the tephra-fall datum (chronohorizon) (e.g., Almond, 1996). Typically, there are additional problems associated with bioturbation and postdepositional reworking (e.g., Austin et al., 2004; Gehrels et al., 2006; Newnham et al., 2007a; Payne and Gehrels, 2010). These difficulties also apply to cryptotephra deposits described below.

Microscopic

Distal tephra deposits, preserved as glass-shard and/or crystal concentrations in peat bogs, lake, marine, or aeolian sediments, or ice-cores, or soils, may be invisible to the naked eye in the field (Lowe, 2011). Such deposits, usually of fine ash

grain-size, are referred to as 'cryptotephra,' from the Greek *kryptein*, to hide, to convey the hidden or concealed nature of these diminutive deposits. Until relatively recently, tephra records reported from sites in Europe were predominantly visible layers of ash, prominent in sedimentary sequences because the individual glass shards are of relatively large size, and/or because shard concentrations in the sediment were extremely high. Although visible ash layers had been correlated to sites distant from volcanic sources – such as the Icelandic Vedde Ash found in Norway (Birks et al., 1996) and the Laacher – see tephra from the Eifel district in Germany (van den Bogaard and Schmincke, 1985), traced as far as Turin in north Italy – the areas of Europe in which tephrochronology could be used as an adjunct to stratigraphical investigations were relatively limited. Andrew Dugmore was the first to identify a cryptic

Figure 4 Distributions of two exceptionally large Pleistocene eruptions: (a) Youngest Toba Tephra (ca. 74 ka BP) erupted from Toba Caldera Complex in northern Sumatra. Isopach values for Toba Tephra are in centimeters (reproduced from Lee M-Y, Chen C-H, Wei K-Y, Lizuka Y, and Carey S (2004) First Toba supereruption revival. *Geology* 32: 61–64, see also Matthews et al., 2012); (b) Lava Creek B (ca. 0.64 Ma) from Yellowstone Caldera, west-central United States of America (reproduced from Izett GA and Wilcox RE (1982) Map showing localities and inferred distribution of the Huckleberry Ridge, Mesa Falls and Lava Creek ash beds (Pearlette family ash beds) of Pliocene and Pleistocene age in the Western United States and southern Canada. *US Geological Survey Miscellaneous Investigations Series Map I-325* scale 1:4 000 000).

Icelandic tephra in the United Kingdom (Dugmore, 1989a). The later development of a density separation (flotation) method (Turney, 1998) led to the detection of the 10.3 ^{14}C ka BP Vedde Ash in Scotland, and subsequent studies further demonstrated the presence of microscopic glass shards in sediments well beyond the limits of visible tephra records. Since its discovery in Scotland, the Vedde Ash has been identified in Scandinavia, The Netherlands, and NW Russia (Figure 10; see also Blockley et al., 2007). More than 34 different tephras have been recognized in western Europe and the NE Atlantic region spanning the period between ca. 18.5 and 8 ^{14}C ka BP (Davies et al., 2002). These originated from four main volcanic provinces: Iceland, the Campanian district in Italy, the Eifel district, and the Massif Central in France, and collectively offer

considerable potential for developing precise tie lines between ice, marine, and terrestrial records, and hence a basis for correlation that is independent of other dating methods (Turney et al., 2004; Lane et al., 2012). The observed occurrence of cryptotephra from the Icelandic Eyjafjöll AD 2010 eruption provides an important modern analogue for understanding ash dispersal patterns over Europe and the NE Atlantic region in the past, particularly in relation to the critical role of weather patterns, as well as evaluating the dispersal of different eruptive phases in widely separated localities (Davies et al., 2010).

Chemical traces

A single eruption injects various quantities of insoluble silicate matter (tephra) and gases into various levels of the

Figure 5 Time series of SO_4^{2-} , Cl^- , and microparticle concentration (N) in GISP2 ice core, showing peaks assigned to Mount Mazama eruption fallout. Reproduced from Zdanowicz CM, Zielinski GA, and Germani MS (1999) Mount Mazama eruption: Calendrical age verified and atmospheric impacts assessed. *Geology* 27: 621–624.

atmosphere. Being larger and heavier than the aerosols produced by the oxidation of gases released, the ash components quickly settle out and consequently have limited climate influence except for areas in the immediate vicinity of the eruption. In contrast, aerosols such as H_2SO_4 (oxidized from SO_2 and H_2S) will remain in the stratosphere for several years providing a source for climate disturbances as well as providing a nucleus for various chemical reactions that can lead to ozone loss. The El Chicon (1982) and Mount Pinatubo (1991) eruptions illustrated that volcanic aerosols can potentially have a significant impact on regional to global atmospheric concentrations as well as an influence on global mean temperature. Ice-core parameters that document the presence of volcanic aerosols include SO_4^{2-} and electrical properties of ice such as

conductivity, which provides a measure of total acids and total salts. More recently, volcanic records in ice cores have reached a new level of detail through the measurement of both SO_4^{2-} and electrical properties on the Greenland GISP2 and GRIP ice cores. In some cases, sparse, very fine-grained ($<20\ \mu\text{m}$) glass shards from widely dispersed tephra are found within acid layers (see Figure 5; see also Abbott and Davies, in press). The longest existing continuous record of volcanism from an ice core is the 110 ka record from the GISP2 core which reflects high-sulfur-producing equatorial and Northern Hemisphere eruptions. The ability to obtain volcanic records from both the Greenland and Antarctic ice cores enhances the capabilities of detecting past eruptions that may have had a global impact (e.g., equatorial Tambora 1815 and Krakatau

Figure 7 Road cutting near Rotorua, North Island, New Zealand, showing tephra layers and associated buried paleosols (dark brownish to yellowish-brown horizons) dating back ca. 18 cal ka. Deposition of each tephra was followed by a period of quiescence and soil formation; then the soil was buried by tephra from a new eruption. German explorer Dr Ernst Dieffenbach described a site near here in 1839, the first recorded description of tephra in New Zealand. All the tephra apart from Taupo (Tp) were erupted from nearby Okataina caldera. Names and eruption ages are as follows (volcano name in brackets): Tr, Rotomahana Mud AD 1886 (Tarawera); Ka, Kaharoa ca. AD 1314 (Tarawera); Tp, Taupo ca. AD 232 (Taupo); Rw, Rotokawau ca. 3.6 cal ka BP (Rotokawau craters); Wk, Whakatane ca. 5.5 cal ka BP (Haroharo); Mk, Mamaku, ca. 8.0 cal ka BP (Haroharo); Rm, Rotoma ca. 9.5 cal ka BP (Haroharo); Wh, Waiohau ca. 14 cal ka BP (Tarawera); Rr, Rotorua ca. 15.6 cal ka BP (Okareka/Haroharo); Rk, Rerewhakaaitu (pale layer within grayish loess deposits) ca. 17.6 cal ka BP (Tarawera). Photograph by B.E. Green in Hodder et al. (1990).

1883 eruptions). When the signal is found in only one of the polar regions, a source eruption from the hemisphere of the ice core is implied. That is the case for the Icelandic Laki (1783) and Alaskan Katmai (1912) eruptions, signals found in almost all Greenland ice cores, and for the New Zealand Tarawera eruption (1886) signal found in Antarctic cores (Delmas, 1992; Zielinski, 2000; Figure 11).

Mineralogical and Geochemical Characteristics

The use of tephra layers to define isochronous horizons, traceable between different stratigraphic successions, is only

Figure 8 Tephra sequence deposited between 1.3 and 2.0 ^{14}C ka BP, 14 km NNE of Kliuchevskoi volcano summit, Kamchatka, Russia. The thick, upper light-colored tephra layer is sourced from Shiveluch volcano (SH3) with an age of ~ 1.4 ^{14}C ka BP, and the thick, lower pale brown tephra layer is sourced from Ksudach volcano (KS1) with an age of ~ 1.8 ^{14}C ka BP. Both tephra are prominent Holocene marker beds throughout Kamchatka and have been described in Braitseva et al. (1997). possible if each horizon has unique characteristics, which not only aid detection and identification, but also reduce the possibility of spurious correlations between tephra of different ages but with similar physical and geochemical properties (Lowe, 2011).

Ferromagnesian mineral assemblages

Ferromagnesian mineralogical assemblages of a tephra horizon $< \sim 100$ km from the eruption center can aid in the identification of source volcano (Froggatt and Lowe, 1990). Tephra derived from the same center, or from several centers with similar geological characteristics and histories, will tend to have similar mineralogical composition, but changes through time are also known. Tephra from typical calc-alkaline volcanoes contain one or more of the mineral phases orthopyroxene, clinopyroxene, amphiboles (hornblende and cummingtonite), and biotite. Volcanoes that erupt peralkaline magmas may contain sodic phases such as aegirine, riebeckite, ferrohedenbergite, and aenigmatite. The minerals can be easily examined as loose grains (crystals) under a binocular or petrological microscope after the tephra sample has been crushed and wet sieved to remove particles < 63 μm in size. Distal tephra

Figure 9 (a) Laterally continuous tephra bed within cross-stratified highly fossiliferous shallow marine sandy siltstones. Inset: Extensive burrowing and sharp but irregular upper and lower contact. beds (>100 km from source) are often mineral-poor because of atmospheric sorting during transport. For such samples, the ferromagnesian minerals can be concentrated using heavy liquids or electromagnetic methods. Problems with the use of mineralogies include the total dissolution of some minerals (e.g., biotite) and preferential dissolution of orthopyroxene relative to hornblende in some acid peat settings, resulting in incorrect ratio estimates (Hodder et al., 1991). Platy minerals such as biotite are easily winnowed from deposits that have been subjected to wind or water action. Therefore, the presence of a particular mineral is more instructive than its absence. Because many tephra beds contain similar mineral assemblages, it is only practical to use mineralogy as a tool when accurate stratigraphic control is available. In the search for a more diagnostic basis for distinguishing between tephra beds of similar mineralogy, researchers now routinely utilize geochemical techniques to fingerprint tephra mineral components, an approach made increasingly more precise and accessible through the development of high-precision analytical instruments with high spatial resolution.

Glass geochemistry

The chemical composition of volcanic glass (e.g., Figure 12) provides a well-established means for the stratigraphic

Figure 10 Known distribution of the Vedde Ash (VA), Laacher See (LST), and Neapolitan Yellow Tuff (NYT). The locations of the principal volcanic centers that were active during the period ca. 18.5–8 ^{14}C ka BP are also identified. Reproduced from Davies SM, Branch NP, Lowe JJ, and Turney CSM (2002) Towards a European tephrochronological framework for Termination 1 and the Early Holocene. *Philosophical Transactions Royal Society of London A* 360: 767–802.

correlation of tephra. Numerous studies attest to the application of electron microprobe (EMP) analysis to enable geochemical fingerprinting of tephra by their major element abundances. Nine major elements determined by EMP are routinely analyzed (e.g., Shane, 2000). However, it is imperative to use recognized standards and to check analyses against reference samples, assay of which should be published alongside newly acquired data (Kuehn et al., 2011; Lowe, 2011; Westgate et al., 2008). Many tephra beds can be distinguished on the basis of a few glass major element oxides such as FeO_t and CaO (wt%) (Figure 13(a)). Within-tephra homogeneity and compositional differences between tephra deposits reflect derivation from separate magma batches that lacked pre-eruptive compositional gradients. Homogeneous glass populations, derived from a single eruptive event, are characterized by low standard deviations and tight clustering of data points on element–element plots (Figure 13(b)). Some tephra have major element compositions that comprise several discrete populations (Figure 13(c) and 13(d)) or a range of compositions (e.g., Pyne-O'Donnell et al., 2008; Shane et al., 2008). Once recognized, such compositional variability can enhance correlation by providing additional fingerprinting criteria, but sampling from the full spatial and temporal range of deposits of an eruptive sequence is required (Shane et al., 2008).

Figure 11 Comparison of eruption-derived acid fallout deposited in Greenland and Antarctic snow over the last 210 years. On the right-hand side, the acidity profile (electrical conductivity measurements (ECM)) obtained at Crete, central Greenland, is shown. On the left-hand side are shown the sulfate measurements obtained at Dome C. The following eruptions are identified: Agung (AG), Santa Maria (SM), Tarawera (TA), Krakatoa (KR), Coseguina (CO), Tambora (T), Unknown (UN), Hekla (HE), Katmai (KA), and Laki (LA). Reproduced from Delmas RJ (1992) Environmental information from ice cores. *Reviews of Geophysics* 30: 1–21. Copyright 1992, American Geophysical Union.

Redeposited and/or mixed tephra beds can also be distinguished by glass major-element compositional analysis, which indicates when a glass population most likely represents the mixed products of separate eruptive events. Increasingly, single shard, laser ablation, inductively coupled, plasma mass spectrometry (LA-ICP-MS) is being used to provide high-quality, grain-specific trace element data that can aid in the correlation of tephtras (Pearce et al., 2004, 2007, 2008, 2011). Furthermore, the high spatial resolution offered by single-shard analysis by LA-ICP-MS provides the potential to shed light on processes operating during fractional crystallization and evolution of magma (e.g., Allan et al., 2008).

Some studies have added a cautionary note regarding the postdepositional chemical instability of some glass, especially basaltic, and hence potential for miscorrelation (Blockley et al., 2005; Pollard et al., 2003).

Fe–Ti oxides and silicate mineral chemistry

Grain-specific analyses of Fe–Ti oxides and estimates of eruption temperature (T) and oxygen fugacity (fO_2) (oxidation state of the magma) have been used to fingerprint tephra deposits (see Shane, 1998; Figure 14). The composition of the titanomagnetite phase is particularly diagnostic of eruptive center and can be used to distinguish many tephra beds from

Figure 12 Scanning electron micrograph images of mid-Holocene rhyolitic glass shards extracted from a peat core in North Island, New Zealand. Such shards can be polished and analyzed by EMP to identify their source and likely correlative. Reproduced from Gehrels MJ, Lowe DJ, Hazell ZJ, and Newnham RM (2006) A continuous 5000-year Holocene cryptotephrostratigraphic record from northern New Zealand: Implications for tephrochronology and volcanic hazard assessment. *The Holocene* 16: 173–187.

the same volcano. TiO_2 is the most variable major oxide, ranging between ~6.5 and 16 wt% for different eruptions. MgO , MnO , and Al_2O_3 may vary by a factor >2 in both the spinel and rhombohedral (ilmenite) phases between different tephra beds. The compositional range within individual eruptive units is narrow if the tephra was derived from a thermally homogeneous magma. However, some tephtras are derived from mingled magmas and thus display a wide compositional range in Fe–Ti oxides. Individual eruptive events that display uniform Fe–Ti oxide compositions and thus narrow ranges in T (<~20 °C) and log fO_2 (<~0.5) allow these features to identify individual magma batches. These criteria can help distinguish tephra deposits of similar bulk or glass composition that originated from the same volcano, and can be used to identify the volcanic source.

Figure 13 Examples of the glass composition in rhyolitic tephra beds determined by electron microprobe analysis. (a) Plot of CaO versus FeO_t (wt%) compositions of glass shards from six selected tephra layers showing their compositional homogeneity; (b) CaO versus FeO_t (wt%) compositions of glass shards of all named and stratigraphically discrete tephra beds in Wanganui Basin, New Zealand. Error bars represent 1 standard deviation. Gray dots represent all Wanganui analyses (reproduced from Pillans B, Alloway BV, Naish T, Westgate JA, Abbot S, and Palmer AS (2005) Silicic tephra in Pleistocene shallow marine sediments of Wanganui Basin, New Zealand. *Journal of the Royal Society of New Zealand* 35: 43–90; see also Figure 24). Examples of compositional heterogeneity found in individual tephra beds: (c) Two (AT-498, -404, and -374) and three (AT-492) discrete compositional groups. (d) Dominant shard population with a single outlier shard (AT-568 and -485) and near continuum of compositions (AT-273 and -377). All examples (except Figure 13(b)) come from ODP cores retrieved east of New Zealand (e.g., Alloway et al., 2005).

Figure 14 The minor element composition of spinel (Al₂O₃-rich phase) and ilmenites (Al₂O₃-poor phase) in rhyolite tephra from Okataina Volcanic Centre (Shane, 1998), demonstrating their fingerprinting ability. Also shown is estimated eruption temperature based on equilibrium between spinel and ilmenites.

Silicate minerals, on the other hand, have a set crystal structure and only limited chemical substitutions are possible. Thus, in many silicic tephra deposits such minerals cannot be used to distinguish between eruptive events. In addition, the most common phases often display considerable composition range within individual deposits, such as orthopyroxene (En range >10%) and are commonly zoned, for example, plagioclase (An range 10–20%). The compositions of amphiboles and pyroxenes have been used successfully in some studies, however, to support tephra identification (e.g., Cronin et al., 1996). Biotite, which is common in tephra with high-K glass (>4 wt% K₂O) can also be valuable (Shane et al., 2003). The FeO/MgO ratio in biotite does not correlate with FeO/MgO in the coexisting glass phase so that tephra beds with similar glass compositions can be discriminated by their different biotite compositions. Some individual tephra deposits display sequential changes in biotite composition that allow separate phases of the eruption to be identified, greatly increasing the potential precision for correlation. In addition, devitrified lavas that are unsuitable for glass analysis can be correlated to coeval tephra deposits by their biotite compositions.

Chronology

Direct Dating of Tephra

Historical accounts: eye-witness descriptions of tephra falls/eruptions

Historical accounts have provided accurate eruption years for many eruptions in countries where volcanic activity is common, in particular during the past 200–300 years. The most widely known historical account was contained in two letters from Pliny the Younger to the Roman historian Tacitus, describing the death of his uncle, the famous scholar Pliny the Elder, by asphyxiation while observing the AD 79 eruption of Vesuvius. Yet the 1815 eruption of Tambora (Sumbawa, Indonesia), the largest and deadliest eruption in recorded history, had little scientific impact because of the volcano's remote location and slow global communication at the time. No scientific expedition was dispatched to Tambora until 1847, and another 8 years passed before an expedition report was published. In contrast, the Krakatau (Sunda Straits, Indonesia) eruption in 1883 was the first to be quickly and widely reported because the telegraph system had been developed by then.

There are many countries around the world where eruptions have been documented through oral or written accounts. Frequently, the correlation between an eruption described in such accounts and a particular volcanic eruption or resulting lava flow or tephra deposit may be obvious (e.g., Etna, 1669; Krakatau, 1883), and in some cases, prehistoric oral accounts (legends) can be related to independent tephrostratigraphic and archaeological evidence (e.g., Cronin and Neall, 2000). More often, however, correlation between recorded eruption years and tephrostratigraphy is not a straightforward one. This is especially the case where there are numerous active volcanoes in isolated terrains, such as in Iceland. Historical accounts kept by community officials or by annalists (e.g., *Annales Islandici*; Storm, 1888) have provided dates for >100 eruptions in Iceland during the last nine centuries. The accounts vary from a few words to detailed descriptions of eruption sites and areas affected by tephra fall. Written sources have documented the dates of all historical eruptions of Hekla volcano, the majority of the historical eruptions of volcanoes below the ice caps of Vatnajökull and Myrdalsjökull, and the eruptions of other volcanoes in Iceland and off the southwest and northern coasts. The quality of the sources is variable, with contemporary documentation being the most reliable (Larsen and Eiríksson, 2008). Eruption locations are sometimes clearly described, but many are inaccurate, some are obviously wrong or vague or the location is not specified, making correlation between written and tephrostratigraphic records difficult. A detailed, spatially extensive stratigraphic record is therefore a prerequisite to validate eye-witness accounts, helped by documenting field and laboratory characteristics. Pairs or series of tephra layers are favored over individual layers. Thus, the first Icelandic tephra layers securely dated were those of the Hekla (AD 1693), Katla (AD 1721), and Hekla (AD 1766) eruptions (Thorarinsson, 1967).

Fission-track dating

Fission-track (FT) dating of tephra beds using coexisting zircon and glass phases has played a significant role in advancing the

stratigraphy and chronology of Plio-Pleistocene successions in New Zealand, United States of America, Canada, Japan, and East Africa. However, application of the zircon FT technique to the dating of distal tephra was often hindered by low abundance of zircons, fine grain size, and presence of detrital grains. Volcanic glass shards are typically the most abundant component of such sediments and commonly the only datable phase. Up until recently, hydrated glass shards were seldom used to determine the age of Quaternary volcanic rocks because glass has a propensity for partial fading (natural size reduction) of fission tracks even at ambient temperatures and because of the time-consuming nature of establishing correction procedures. During the late 1970s, FT dating of volcanic glass shards provided the first numerical ages for tephra layers in New Zealand and United States of America. However, the glass ages could not be considered reliable unless the glass was checked for FT fading because the latter would lead to lower apparent ages. The isothermal plateau fission track (ITPFT) dating technique applied to hydrated glass shards was developed in the late 1980s (Westgate, 1989). This technique corrected for the effects of partial track fading by heating at 150 °C for 30 days. Accurate and precise ITPFT-ages were obtained consistently on tephra-derived glass provided that it had experienced simple thermal histories. The precision is better than 10% of the mean age for most samples, but can be improved considerably if the sample is counted several times by different operators. A weighted mean can then be derived.

The glass-ITPFT technique is particularly well suited to the dating of distal rhyolitic tephra, permitting a direct and detailed comparison of stratigraphic and chronologic data. Since then, the ITPFT technique has been widely applied to a variety of proximal to distal depositional settings and environments in the United States of America (e.g., Preece et al., 1999), western Canada, New Zealand (e.g., Alloway et al., 1993; Pillans et al., 2005; Shane et al., 1996), Japan, East Africa, and Indonesia (e.g., Alloway et al., 2004; Chesner et al., 1991). The use of this dating technique, especially when combined with other tephrochronological tools, has led to important advances in Quaternary stratigraphy and regional to interregional correlation.

^{40}Ar – ^{39}Ar dating

The $^{40}\text{Ar}/^{39}\text{Ar}$ technique provides an opportunity to obtain high-precision ages on young tephra deposits. Notable applications include the precise dating of tephra within hominid-bearing deposits in north-eastern Africa (e.g., Walter, 1994; Walter et al., 1991). In New Zealand, the $^{40}\text{Ar}/^{39}\text{Ar}$ dating technique has played a pivotal role in determining the chronology and dynamics of caldera-forming ignimbrite eruptions in the central Taupo Volcanic Zone over the last 1.6 Ma (Houghton et al., 1995) and in the older Coromandel Volcanic Zone (Briggs et al., 2005). Initial $^{40}\text{Ar}/^{39}\text{Ar}$ studies performed step-heated Ar-release experiments on bulk feldspar and sanidine separates, and laser fusion analysis on mineral subsamples to obtain age spectra and isochrons. A precision of about ± 30 ka for Quaternary-aged plagioclase and better than 1% on sanidine was obtained. However, the use of single-crystal laser fusion (SCLF) has revealed the common occurrence of contaminants and partially degassed relict crystals with individual pumice blocks sometimes containing crystals

with a range of ages (e.g., Gansecki et al., 1998). Such studies have shown that an accurate age for some tephra deposits can be assessed only by grain-specific techniques. The SCLF $^{40}\text{Ar}/^{39}\text{Ar}$ technique has been applied to tephra deposits as young as the Holocene age (Chen et al., 1996). Because of the small volume of Ar involved in SCLF, K-rich phases are commonly required. This limits its application to calc-alkaline volcanic provenances. Unfortunately, the technique has not been widely applied to distal tephra beds because of their fine grain size and crystal-poor character.

Dating Enveloping or Entrained Materials

Radiocarbon dating

Since its advent around 1950, radiocarbon (^{14}C) dating has been the dominant technique for dating tephra layers deposited within the past 50–60 ka. To provide accurate ages, ^{14}C dating has three key requirements.

1. Samples containing carbon, including wood, leaves, twigs, charcoal, peat, lake sediment, pollen, or shells, must be contemporaneous, or very nearly so, with the eruption that generated the tephra, that is, terrestrial or aquatic plant material metabolizing at the time of the eruption was killed by that event and either (a) entrained in the deposit (as in the case of charcoal or carbonized wood within hot pyroclastic density currents) (Figure 15(a)), or (b) directly overlain and hence buried by the deposit, or (c) directly underlain by the deposit (e.g., tephra fallout on a peat bog that subsequently resumed its growth) (Figure 15(b)).
2. Samples must contain sufficient ^{14}C – in excess of background levels – to enable an age to be derived, otherwise a ‘minimum’ age is the result.
3. Radiocarbon ages obtained must be calibrated, that is, converted to calendar years rather than ^{14}C years which, because of fluctuations in ^{14}C productivity in the atmosphere and other factors, do not exactly match calendar (solar) years. Calibrations on terrestrial samples spanning the past 50 cal ka are made using an internationally agreed set of calibration curves (IntCal09) based on cross-matching ^{14}C ages against tree-ring-based sequences to 12.4 cal ka ago, and laminated marine and lake sediments and U-series-dated corals, speleothems, and foraminiferal deposits (Reimer et al., 2009).

Ages are measured by two methods: (1) *radiometric laboratories* synthesize either benzene (C_6H_6) or CO_2 and count the decay of ^{14}C in these over time (called beta counting) and (2) *accelerator mass spectrometric (AMS) laboratories* synthesize graphite (or CO_2) and count the relative number of ^{14}C atoms directly (the isotope ratio of ^{14}C relative to that of ^{13}C or ^{12}C is measured). Both methods have been widely used for dating tephtras, the AMS system increasingly so where sample sizes are tiny or where separate components, such as pollen grains within sediments, are dated to help acquire better age estimates for associated tephra layers (e.g., Newnham et al., 2007a).

Radiocarbon ages on tephtras are subject potentially to a wide range of errors (see Walker, 2005). However, only laboratory counting statistics (normally increased by a laboratory ‘error multiplier’) are reported as part of the age measurement,

conventionally in years BP and at 1 standard deviation (1σ). The ‘present’ refers to 1950. Reported 1σ errors, representing 68% probability, may range from ± 15 years for high-precision ages on optimal material of late Holocene age to ± 2 ka or more for late Pleistocene samples or for samples containing small amounts of carbon. Although ^{14}C laboratories provide ages routinely with a 1σ error term, there is a trend now for ages on tephtras to be evaluated at 2σ , representing 95% probability (Hajdas et al., 2006; Lowe et al., 2008; Walker, 2005).

Wiggle-match dating using dendrochronology or depositional age modeling using peat/lacustrine stratigraphy

Wiggle-match dating is the process of matching a time-series of ^{14}C samples, usually from wood or peat or lacustrine deposits, to the shape of ^{14}C calibration curves to derive a more precise age estimate for an eruption event than would be otherwise obtainable from ^{14}C ages or dendrochronology. The matching process is called flexible age-depth modeling where it involves sediments (Lowe, 2011). Hogg et al. (2003) fitted five contiguous ^{14}C ages on decadal blocks from a 50-year-old tree killed

Figure 15 (a) Carbonized log entrapped within pyroclastic density current deposits (Taupo Ignimbrite) near Taupo, North Island, New Zealand. Such logs have provided numerous ^{14}C ages for the Taupo eruption that generated the ignimbrite (Froggatt and Lowe, 1990; Wilson, 1993; Hogg et al., 2012). Photograph: Brent Alloway. (b) Distal rhyolitic tephra-fall layer (white) preserved within peat near Hamilton, North Island, New Zealand. The age of the mid-Holocene ash layer can be obtained by dating the encapsulating peat using the ^{14}C method (Hogg et al., 1987). Photograph courtesy of Maria Gehrels, University of Plymouth.

by the Kaharoa eruption of Mt. Tarawera, New Zealand, to the wiggles of the high-precision Southern Hemisphere calibration curve. Once all five ages were 'locked' onto the curves, it enabled the estimation of the death of the tree, and thus the date of the Kaharoa eruption, at AD 1314 $\pm$ 12 from the date calculated for its outermost ring. The eruption of the Greek volcano of Thera (Santorini) in the Aegean Sea, and the associated widespread tephra, was dated to 1627–1600 BC using wiggle-match dating of wood from a chair burnt during the eruption (Galimberti et al., 2004). In a study of the Kaipo bog sequence in New Zealand, improved ages on late-glacial and Holocene tephra layers intercalated with peat deposited since ca. 18 cal ka were derived using a Bayesian-based age-depth model wiggle-matched against the IntCal04 curves (Hajdas et al., 2006; Lowe et al., 2008). Wiggle-match dating/flexible age-depth modeling have also been conducted on tephra-bearing lake sediments in United States of America, central Europe, and Scandinavia (Blockley et al., 2008; Kuehn et al., 2009; Wohlfarth et al., 2006).

Luminescence dating

Thermoluminescence (TL) and optically stimulated luminescence (OSL) dating have become widely used in Quaternary studies. Many applications are still experimental, however, and specialists disagree as to the reliability of these methods with certain materials and over certain time ranges. Direct luminescence dating of tephra beds is uncommon but some ages have been determined and compared with independent numerical ages to show that purified fine-silt-sized glass can be reliably dated over the age range 5–450 ka (Berger, 1992). More often, luminescence dating is applied to fine-grained mineral fractions of bracketing paleosol-loess deposits. In one such example, TL dates from late Pleistocene loess successions in eastern Washington, USA, indicated that the ages of tephra interbeds were significantly older than those implied by earlier ^{14}C dating, suggesting a much longer eruptive history (>50 ka) for Mt. St. Helens than previously accepted (Berger and Busacca, 1995; Figure 16). Tephra ages have also been determined by TL dating of bracketing loess from sites in Alaska (Berger et al., 1996), New Zealand (Berger et al., 1992), and Japan (Watanuki et al., 2005). For example, one of the Sheep Creek group of tephra, SCt-F in the Fairbanks area, was dated at 190 ka (Berger et al., 1996; Westgate et al., 2008). In North Island, New Zealand, the Rotoehu Ash was OSL dated at ca. 45 cal ka BP (Lian and Shane, 2000), in approximate agreement with previous ages deduced from several other methods (Danisik et al., 2012).

Luminescence dating complements ^{14}C dating over its ~60-ka age range, and allows ages to be obtained when no carbon is available. Generally, there is good agreement between the two techniques (e.g., Demuro et al., 2008) but discrepancies in others (e.g., Lowe et al., 2010). Large sets of luminescence ages from the same stratigraphic horizon (from which a measure of reproducibility of luminescence dating can be derived) are not commonly obtained. Beyond the ~60-ka limit to ^{14}C dating, TL and OSL dating provide an extension into the late Quaternary where methods based on radioactive decay (K/Ar, U-series, and fission track) can be applied for comparison. One of the most comprehensive multimethod comparisons was applied to Rangitawa Tephra (Pillans et al.,

Figure 16 TL ages (ka) for the samples of loess and Mt. St. Helens tephra (Set S, MSH S; Set C, MSH-C; Early Mt. St. Helens, EMSH). Reproduced from Berger GW and Busacca AJ (1995) Thermoluminescence dating of Late Pleistocene loess and tephra from eastern Washington and southern Oregon, and implications for the eruptive history of Mount St. Helens. *Journal of Geophysical Research* 100: 22, 361–22, 374. Copyright 1995, American Geophysical Union.

1996) – a 350-ka marine and terrestrial interregional tephra marker bed in New Zealand dated by luminescence, fission track (glass and zircon), K/Ar, Ar/Ar methods, and orbital tuning (Figure 17).

Paleomagnetism

In many studies, numerical ages derived from glass-ITPFT, SCLF Ar/Ar, and TL methods are used in conjunction with magnetostratigraphic information. This combination is helpful because the age of geomagnetic polarity transition zones is well known for late Cenozoic time and provides an independent check on the reliability of numerical age estimates. The geomagnetic polarity sequence registered in the bracketing sediment is itself a useful signature for correlation purposes. For example, the identification of relatively short-lived polarity subchrons, such as the Jaramillo Normal Subchron (1.07–0.99 Ma), has greatly facilitated the construction of a tephrostratigraphy in the basins of the southern North Island (Pillans et al., 2005; Shane et al., 1996) and loess cover-beds in the Fairbanks region of central Alaska (see Preece et al., 1999; Figure 18). Magnetic measurements on ignimbrites and widespread ash-fall deposits in Japan provided the means both to correlate these units and to link the source volcanic area with marine and other sequences over a distance of 1000 km (Hayashida et al., 1996).

Applications of Tephrochronology

Case Studies

Volcanic hazard assessment and eruption frequency from long tephra records

Tephrochronological studies help to establish the recurrence intervals of major episodes of volcanic activity. Detailed tephrostratigraphic records provide a basis for predicting the likely frequency and magnitude of volcanic activity in the

Figure 17 (a) Summary of numerical age determinations on Rangitawa Tephra, with 1 SD error bars plotted (reproduced from Pillans B, Froggatt P, Kohn BP, et al. (1996) Multi-method dating comparison for mid-Pleistocene Rangitawa Tephra, New Zealand. *Quaternary Science Reviews (Quaternary Geochronology)* 15: 641–653). future. A notable example is the tephra hazard zonation map for Mt. St. Helens that was produced 2 years before the May 1980 eruption (Crandell and Mullineaux, 1978). The zones reflected the thickness-distance relations of three past tephra-fall episodes representative of eruption magnitudes and dominant wind patterns and speeds in the Pacific north-west. The boundaries of the zones were placed arbitrarily at distances of 30, 100, and 200 km from the volcano and were intended to aid users in locating areas with respect to potential tephra thicknesses. This zonation map should probably have been

extended to cover distal areas >200 km downwind in light of the wide distribution and impacts of thin tephra-layer accumulation that ensued. Nowadays, numerical and probabilistic models have been developed for use in estimating the extent and thickness of potential tephra falls and may aid in delimiting tephra-hazard zones (e.g., Bonadonna et al., 2002; Hurst and Smith, 2004). The inputs to the models include wind data and seasonality, eruption rate and duration, column height, grain-size distribution, and settling velocities.

Long tephra records can contribute significantly to an understanding of eruption frequency and tephra dispersal. A notable example is the tephrostratigraphic record from Lago Grande di Monticchio in southern Italy (Wulf et al., 2004). Here, 340 distal tephra layers are preserved within 72.5 m of lacustrine sediments deposited over the last 100 ka (Figure 19). Most tephras ($n=313$) preserved within this long core are derived from volcanic eruptions of the Campanian province, which still represents an area of volcanic risk for the Naples metropolitan area. Other tephras are related to high-explosive events of Roman and Sicilian-Aeolian volcanoes ($n=17$) or cannot be correlated with any distinct volcanic source ($n=10$). In addition to this continuous, high temporal resolution record of climate and environmental change from a maar lake, the intercalated tephra sequence provides new information about the eruptive tempo of explosive Italian volcanoes and dispersal of tephra.

Until recently, assessments of volcanic hazards for the city of Auckland (New Zealand's largest metropolitan area

Figure 19 Sedimentology and tephrostratigraphy of composite profile LGM-B/D/E/J from Lago Grande di Monticchio. with ~1.5 million people) focused entirely on the threat from the local basaltic Auckland Volcanic Field (AVF), such threats being assessed most recently using a Bayesian-statistical framework (Lindsay et al., 2009). The threat of inundation by tephra fall from distant rhyolitic and andesitic centers in central and western North Island (~200–260 km away) was not considered in any regional or local authority plan until Newnham et al. (1999) demonstrated that such a threat existed. Since then, new long records obtained from Auckland maars have further highlighted the region's vulnerability to frequent impact by ash fall, distal, and local (Sandiford et al., 2001; Shane and Hoverd, 2002; Molloy et al., 2009; Figure 20). Source volcanoes for distal tephra include the rhyolitic Taupo (TVC) and Okataina (OVC) volcanic centers, the peralkaline Tuhua Volcanic Centre (TuVC) of Mayor Island, and the andesitic Egmont (EgVC) and Tongariro (TgVC) volcanic centers. A total of 106 different tephra layers from local and distant

Figure 20 (Continued)

volcanoes (>0.5 mm thick) in the last 80 ka have been recorded in the Auckland maars, an average recurrence of ca. 755 years (Molloy et al., 2009). These comprise 52 events from EgVC (1 per 1.5 ka), 24 AVF events (1 per 3.5 ka), 21 Taupo Volcanic Zone rhyolite (TVC and OVC) events (1 per 3.8 ka), 7 TgVC events (1 per 11.4 ka), and 2 TuVC events (1 per 40 ka). Unrecognized cryptotephra (<0.5 mm) are also likely to be present in the cores. Such cryptotephra also potentially have significant implications for hazard assessments as exemplified by the 1995–96 eruptions of Ruapehu Volcano. Tephra from these eruptions disrupted aviation at Auckland but did not leave a macroscopic layer. Most recently, Newnham et al. (2010) identified an increase in respiratory-related mortality in Auckland (also Hamilton) as a possible consequence of the effects of diffuse, fine-grained ash fallout from the 1996 Mt. Ruapehu eruptions. The Auckland study indicates that volcanic hazard assessment based on distal tephra records may be applicable to many large cities

elsewhere that are not currently considered at risk from volcanism (Magill and Blong, 2005; Magill et al., 2006; Newnham et al., 1999).

Geomorphic and landscape reconstruction

Well-developed regional and interregional tephrochronological frameworks can contribute to an understanding of many environmental issues. The main advantage that tephrochronology brings to interdisciplinary paleoenvironmental research is the unparalleled precision and confidence with which disparate terrestrial and marine records can be correlated and dated. An excellent example of this occurs in the North Island of New Zealand which has a history of large volcanic eruptions spanning the entire Quaternary. The biggest eruption in the Taupo Volcanic Zone in the past 60 ka was the Oruanui (or Kawakawa) eruption (Wilson 2001; Figure 21(a) and 21(b)) that occurred ca. 25.3 cal ka BP (Vandergoes et al., in press) during the extended Last Glacial Maximum (LGM). With a

bulk volume of $\sim 1200 \text{ km}^3$ (530 km^3 as magma), the eruption formed the modern Taupo caldera and generated an ignimbrite and very widespread tephra-fall deposits. The preservation of this tephra in loess deposits, in alluvial/colluvial gully fills, and on river terraces, and its absence from unstable sites, have permitted a detailed assessment of geomorphic activity and landscape response during the LGM (Pillans et al., 1993; Manville and Wilson, 2004; Figure 21(c)). Pollen data for sediments associated with products of the Oruanui eruption, and those ^{14}C dated in the range ca. 17–23 ^{14}C ka BP, have also assisted in determining LGM vegetation in northern, central, and southern parts of the North Island and the West Coast of the South Island (Newnham et al., 2007b).

A similar integrated paleoenvironmental study has been achieved for another key tephra in New Zealand, Rerewhakaaitu Tephra (Figure 21(a)), erupted from Mt. Tarawera volcano ca. 17.6 cal ka at a time of major environmental change. Terrestrial evidence, based on fluvial aggradation and downcutting relationships, loess accumulation rates, paleovegetation patterns, and buried soil development and mineralogy, show that marked amelioration of climate occurred at around the

time the Rerewhakaaitu Tephra was deposited (Newnham et al., 2003) (Figures 21(c) and 22). Similarly, marine evidence shows major changes in accumulation rates of sediment and aeolian quartz and abundance of various marine organisms, while foraminiferal oxygen and carbon isotope records indicate that the arrival of the meltwater signal occurred close to, or just after, deposition of the Rerewhakaaitu Tephra. This tephra is thus an important onshore–offshore regional marker for the Last Termination and onset of postglacial environmental conditions.

Glacier advance and retreat, dating of ice

Glaciers in volcanic regions, and the landforms they generate, have been subjected to numerous tephra falls in the Holocene. Tephra layers deposited on glaciers or ice caps are buried in the accumulation areas and may be preserved in the ice. Tephra layers of known age can thus be used to date the ice and contribute greatly to the understanding of glacier dynamics and how glaciers respond to climate and environment.

Iceland is a good example because of frequent eruptive activity and numerous glaciers ranging from small cirque

Figure 21 (a) Map of distributions of Kawakawa/Oruanui (red dashed line) and Rerewhakaaitu (blue dot-dash line) tephra. Isopachs in millimeters. Figure 21 (Continued)

glaciers to ice caps such as 8000 km² Vatnajökull. Early work includes Thorarinsson's studies of an outlet glacier of the Langjökull ice cap where he demonstrated that the most advanced terminal moraine since the retreat of the inland ice in the early Holocene postdated the AD 1693 tephra layer from Hekla volcano (Thorarinsson, 1949) and related to the Little Ice Age (LIA). Dugmore (1989b) used tephrochronology to date the maximum advance of an outlet glacier of Myrdalsjökull ice cap in southern Iceland to the mid-Holocene (>4.5 cal or 4 ^{14}C ka BP) and a gradual retreat to its LIA moraine and the present position. His findings contradicted the opinion that most outlet glaciers in Iceland had their maximum extension during the LIA. Further, tephrochronological dating of moraines in Iceland has confirmed mid-Holocene glacier advances in northern and central Iceland that were locally more extensive than the LIA advances (e.g., Dugmore and Kirkbride, 2001;

Gudmundsson, 1997). Tephrochronology has also been applied to reconstruct the retreat of the inland ice including glacier advances/retreats and the formation of ice-dammed lakes in northern Iceland (Norddahl and Hafliðason, 1992), glacial advances in southern Iceland (Kirkbride and Dugmore, 2008), and ice-cap response to Holocene climate change (Kirkbride and Dugmore, 2006). Tephra layers preserved in the Vatnajökull ice cap have been used to date the ice and to record the eruption history of the volcanoes below the ice cap, revealing that the volcanic activity is intermittent, with a periodicity of 130–140 years (Larsen et al., 1998).

Traces of tephra deposited on the Greenland ice sheet have served as marker horizons in the Greenland ice cores since Palais et al. (1991) were the first to find glass particles in the GISP2 ice core from a known volcanic eruption – that of Öræfajökull AD 1362, erupted from southeast Iceland. Previously, acid fallout

Figure 22 Close-up photo of core from Lake Rotorua (Hamilton, New Zealand) showing darkening in sediment color just above ca. 17.6 cal ka BP Rerewhakaaitu Tephra that reflects an increase in organic content because of reafforestation and amelioration in climate. Note: Colors are for fresh sediment (core oxidized shortly after opening). Reproduced from Newnham RM, Eden DN, Lowe DJ, and Hendy CH (2003) Rerewhakaaitu Tephra, a land-sea marker for the last termination in New Zealand, with implications for global climate change. *Quaternary Science Reviews* 22: 289–308.

from volcanic eruptions had served as time markers in the ice (as noted above), in particular the large acidity peaks relating to the Laki fissure eruptions of 1783–85 (Hammer et al., 1980). Glass shards from several eruptions of known age have now been found in the Greenland ice cores, including glass from the Vatnaöldur tephra (~AD 874), as noted earlier, and the Laki eruptions (Fiaccio et al., 1994). Another example is the detection of the widespread early Holocene Saksunarvatn tephra, dated to ca. 9 ^{14}C ka BP on terrestrial organic material (Mangerud et al., 1986), as a visible ash layer in the GRIP and GISP2 ice cores (Figure 23) where it has been assigned an age of 10.3 ice-core ka (Grönvold et al., 1995; Zielinski et al., 1997). This tephra provides an important tephrochronological linkage between terrestrial, marine, and ice-core records in the North Atlantic region. Tephrae have also been found in Antarctic ice cores (Dunbar et al., 2003; Kyle et al., 1981; Narcisi et al., 2005; Zielinski, 2000).

Sedimentary basin history

The recognition of tephra has been an essential tool for dating lake sediments, shoreline levels, and reconstructing drainage evolution particularly in Plio-Pleistocene pluvial lakes of the Great Basin in south-western United States (e.g., Reheis et al., 2002; Williams, 1994). Precise identification of tephra layers has also proven to be important in understanding the growth and development of sedimentary basins as well as for the correlation of glacio-eustatic sedimentary cycles across marine basins. Wanganui Basin, New Zealand, is one of several Plio-Pleistocene basin margins in the world in which sedimentation matched subsidence through much of its history, resulting in a 5-km thick sequence of predominantly shelf and shallow-water sediment (Pillans et al., 2005). Gentle

neotectonic upwarping of the eastern margin along the plate boundary has produced on-land exposures through as many as 45 superposed cyclothem since 2.5 Ma. This succession represents the most complete, on-land, shallow-marine record of late Neogene climatic and sea-level change yet described. Twenty-eight tephrae are recognized from glass-shard composition and stratigraphic position, and were dated using magnetostratigraphy, orbitally tuned cyclostratigraphy and fission-track (ITPFT) dating (Figure 24). Many tephra deposits can be reliably correlated to distal sedimentary successions

Figure 24 Composite stratigraphic columns for two major sections (Turakina and Rangitikei) in the Wanganui Basin, New Zealand, showing positions of tephra horizons, lithologies, sequence boundaries, and macrofossil LADs and FADs, as well as paleomagnetic samples and boundaries. The onshore cyclostratigraphic records (Sequences 39–16) are compared with the $\delta^{18}\text{O}$ record from Site 1123 retrieved east of New Zealand and the standard equatorial core record obtained from Site 849. LAD, last appearance datum; FAD, first appearance datum. Figure 25 Pinkish-gray tephra beds (dark colored) in light greenish-gray clay to silty clay bearing nannofossil ooze (light-colored) from ODP Site 1124, east of North Island, New Zealand. Photograph courtesy of Lionel Carter, NIWA, Wellington, New Zealand.

throughout the North Island, and in marine cores east of New Zealand obtained by the Ocean Drilling Programme (ODP) (Alloway et al., 2005; Figure 25). The orbitally tuned chronology for the ODP-cores, calibrated by numerical ages on tephra and magnetostratigraphy, enhances inter-regional correlation and provides an important framework for future paleoenvironmental reconstructions.

Hominid evolution

Most of the hominid remains and associated artifacts from the East African rift system have been found in Plio-Pleistocene volcanoclastic sediments. Consequently, the chronology of hominids in East Africa is largely constrained by a combination of regional correlation of tephra layers and isotopic dating (e.g., McDougall, 1985; Walter, 1994; WoldeGabriel et al., 2005). Some eruptions were of sufficient magnitude or duration to generate widespread tephra deposits that occur as a series of dated marker horizons throughout the fossil-bearing deposits of East Africa. Although many of the larger eruptive events have been directly dated, the ages of many other tephra are only constrained by indirect stratigraphic interpolation between dated horizons. The geochemical compositions of volcanic glasses from each eruption are distinctive and provide a definitive means to establish broad tephrostratigraphic correlations. This same tephrostratigraphic approach has been used to extend the East African tephra correlations into the continuous and well-dated marine cores from the western Indian Ocean and Gulf of Aden that contain several macroscopic Plio-Pleistocene volcanic-ash layers, nearly 1000 km east and northeast of hominid localities in Ethiopia and Kenya (Brown et al., 1992; deMenocal and Brown, 1999;

Figure 26). Major-element compositions of glass shards extracted from these marine sediments were used to establish precise tephrostratigraphic correlations into the fossil-bearing East African sedimentary sequences. Moreover, controversy concerning the ages of key tephra marker beds relating to significant temporal junctures in early hominid evolution could be readily tested against correlatives independently dated in orbitally tuned marine records.

Archaeology

Tephrochronology has increasing application in archaeological studies because they form isochronous horizons enabling the correlation of equivalent-aged successions. A good example is the Late Bronze Age explosive eruption of Thera (Santorini) which had a devastating impact on prosperous Cycladic maritime culture and contributed to a major change in the course of Western history (McCoy and Heiken, 2000). The eruption, dated ca. 1627–1600 BC (see the section ‘Chronology’ above), generated a widespread ash found in deep-sea cores in the Aegean, eastern Mediterranean, and Black Sea, as well as in lakes in eastern Turkey (Figure 27). Scattered patches of the ash have also been identified on islands east of Thera and at archaeological sites on Crete – usually reworked into building construction or within Late Minoan destruction debris. Traces have also been identified in Nile delta sediments and in soils of Turkey.

Another example where tephrochronology has advanced archaeological studies is in New Zealand where a key rhyolitic eruptive, Kaharoa Tephra (KT), has helped resolve the controversial timing of initial Polynesian settlement (Lowe et al., 2000; Newnham et al., 1998). Because the settlement occurred so recently in human history – now known to have been within the last 750 years – dating methods including ^{14}C were problematic and two conflicting theories for the timing of settlement emerged, one ‘early’ and the other ‘late.’ KT was erupted in the austral winter of AD 1314 $\pm$ 12 from Mt. Tarawera volcano and dispersed over >30,000 km² of northern and eastern North Island (Hogg et al., 2003). It provides a unique ‘settlement datum’ in three ways. Firstly, the initial deforestation signals, the simultaneous decline in forest trees, and sustained increase in bracken fern (*Pteridium*) and charcoal (as determined from analysis of pollen and spores from sediments containing KT), occurred only a few decades before KT deposition, that is, from late in the thirteenth century to ca. AD 1300 (Figure 28). Secondly, tree-derived seeds nibbled by the Pacific rat, *Rattus exulans*, an introduced predator that accompanied the early eastern Polynesian voyagers to New Zealand, are all <750 calendar years old and, apart from a single exception, have been found only above the KT layer, not below it (Wilmschurst and Higham, 2004; Wilmschurst et al., 2008). Finally, no cultural remains or artifacts have yet been found beneath KT at any archaeological sites (Lowe, 2011; Lowe et al., 2000). This means that such sites must be younger than AD 1314 $\pm$ 12, in close agreement with ages for the earliest archaeological remains in New Zealand including the oldest known at Wairau Bar (South Island) dated using moa eggshell at AD 1288–1300 (Higham et al., 1999). Collectively, the archaeological and paleoenvironmental evidence, linked tephrochronologically by the KT datum, indicates that the earliest Polynesian settlement of New Zealand was ca. AD 1250–1300 (see also

Figure 26 Comparison of radiometric and stratigraphic (interpolated) ages for East African tuffs between 4.0 and 3.4 Ma and their orbitally tuned ages derived from the marine sediment chronostratigraphy at ODP sites 721 and 722 in the Arabian Sea. Reproduced from deMenocal PB and Brown FH (1999) Pliocene tephra correlations between East African hominid localities, the Gulf of Aden, and the Arabian Sea. In: Agusti J, Rook L, and Andrews P (eds.) *Hominoid Evolution and Climatic Change in Europe*, vol. 1. Cambridge: Cambridge University Press.

Figure 27 Regional distribution of tephra from the Thera eruption (shaded area) in the Late Bronze Age. Tephra thickness isopachs are in centimeters. Symbols identify sites where tephra has been identified in cores (triangles) and at archaeological sites (squares). Reproduced from McCoy FW and Heiken G (2000) *The Late-Bronze Age Explosive Eruption of Thera (Santorini), Greece: Regional and Local Effects*, pp. 43–70. Boulder, CO: Geological Society of America, Special Paper 345.

Wilmschurst et al., 2008). The association of KT with early human settlement is similar to the Vatnaöldur tephra or *Landnámsslag* (settlement layer) in Iceland of the mid-870s AD that coincides closely with anthropogenic impacts relating to permanent Nordic settlement.

Conclusions

Since the early pioneering work of Thorarinsson and others, the value of tephra in providing time-parallel marker horizons or isochrons is now well understood. Tephra are routinely detected and identified in both visible and cryptotephra forms, and are used in a diverse range of disciplinary fields including stratigraphy, sedimentology, geomorphology, archaeology, and paleoenvironmental reconstruction over a range of time scales. Tephrochronology is also an essential tool for establishing the frequency/periodicity of volcanic activity and for assessing volcanic hazards.

A number of significant recent advances have contributed to the growing usage of tephrochronology. First, the application of high-precision analytical techniques (e.g., EMP analysis and LA-ICP-MS) has made it possible to obtain detailed major- and trace-element compositions from individual glass shards and for 'fingerprinting' individual tephra beds or tephra

Figure 28 Summary diagram of 12 bracken (*Pteridium*) spore profiles, North Island, New Zealand, containing the Kaharoa Tephra settlement datum (KT). In most profiles, the deforestation signal (increase in *Pteridium* and charcoal, decline of tall trees) occurs at around or after the deposition of KT, but in four (Kopouatai, Papamoa, Kohika, Holden's Bay) it occurs just before, by perhaps a few decades. Ages at the top of each profile are approximate estimates ($\pm$ few decades) for the start of deforestation. Taupo Tephra (Tp) provides a predeforestation datum in most profiles (Hogg et al., 2012); in three other sites, ¹⁴C ages are given. Reproduced from Lowe DJ, Newnham RM, and McCraw JD (2002) Volcanism and early Maori society in New Zealand. In: Torrence R and J. Grattan (eds.) *Natural Disasters and Cultural Change*, pp. 126–161. London: Routledge.

successions of similar mineralogy and/or provenance. The second significant advance has been the detection of cryptotephra well beyond the limits of their previously known visible distribution. Studies of cryptotephra offer considerable

potential for further developing integrated tephrochronological frameworks over much larger areas than previously possible, such as that being developed for Europe and the NE Atlantic region. However, a future challenge of working with

cryptotephra will be quantifying the glass-shard concentration and relating this to ash densities observed and predicted in the atmosphere during an eruptive event (e.g., Eyjafjöll 2010 eruption). Third, the development of the ITPFT dating method has enabled ages to be obtained on many distal tephra that previously were undated because their main component, glass, was regarded as an unreliable medium. Finally, perhaps the most exciting development is the use of tephrochronology, uniquely, to effect more precise correlations between marine, ice-core, and terrestrial records. This application holds the key to testing the reliability of high-precision correlations between sequences and current theories about the degree of synchronicity of climate change at regional to global scales.

Acknowledgments

This chapter is a contribution of the International focus group on tephrochronology and volcanism (INTAV) and of the INTREPID Project (INQUA-0907). The authors thank Lionel Carter, Shane Cronin, Siwan Davies, Peter deMenocal, Maria Gehrels, Brent Green, Grant Heiken, Sigfus Johnsen, Landcare Research, Vern Manville, Tim Naish, Rewi Newnham, Brad Pillans, Vera Ponomareva, D. Reidel Publishing Co., Chris Turney, and Andrei Sarna-Wojcicki, for providing images and figures. We are very grateful to John Lowe, Brad Pillans, Ray Harlow, Alan Hogg, and Jim Begét for helpful reviews or comments. This chapter is dedicated to the memory of Colin George Vucetich (1918–2007) – mentor, friend and pioneering New Zealand tephrochronologist.

Introduction

Radiometric and accelerator mass spectrometric (AMS) analyses for carbon-14 (^{14}C) are fundamentally different as the former is accomplished by measuring the radiation produced by decay of ^{14}C atoms (i.e., β -particles of $E_{\text{max}} = 156 \text{ keV}$) while AMS measures the number of ^{14}C atoms relative to the number of ^{13}C (or ^{12}C). One gram of 'modern' carbon contains approximately 6×10^{10} atoms of ^{14}C and a typical AMS will measure approximately 100 atoms s^{-1} (Fifield, 1999), thereby allowing very small samples to be measured within a short period of time. Radiometric measurement presents a different set of problems:

1. Although the number of atoms per gram is high, the natural activity is extremely low because of the long half-life (5730 years). For modern carbon, the activity is approximately $226 \text{ Bq kg}^{-1} \text{ C}$, that is, on average, only 13.56 atoms in 1 g of modern carbon decay every minute. For old samples with an age of about 50 000 years (the practical limit of the method), the activity is less than $1 \text{ Bq kg}^{-1} \text{ C}$.
2. The ^{14}C β -particles are low energy, therefore, they are not able to penetrate counter materials from the outside and consequently the source of ^{14}C has to be internal.

While AMS undoubtedly has many advantages, radiometric analysis was the only option available until the late 1970s, and it is still used by a large number of laboratories in the ^{14}C -dating community, although the actual number of ^{14}C measurements made will be dominated by the AMS technique.

Irrespective of the method employed, for accurate ^{14}C dating to be achieved, only the ^{14}C that was part of the organism when it died should be measured. Therefore, any extraneous carbon that has subsequently entered the sample (mainly from the burial environment) must be removed. In addition, the fraction that is most suitable for dating must be isolated, for

example, cellulose from wood and collagen from bone. This is achieved by a combination of chemical and physical means, the so-called sample pretreatment. A detailed discussion of pretreatment methods is beyond the scope of this article; however, Mook and Streurman (1983) provide a good starting point. Also, Table 1 lists the approximate weights of samples required for radiometric analysis.

Solid-Source Counting

Modern day radiometric ^{14}C analysis is carried out by either liquid scintillation counting (LSC) or gas proportional counting (GPC); however, the early ^{14}C -dating laboratories adopted

Table 1 Typical percentage carbon contents and weight ranges of raw samples required for radiometric ^{14}C age measurement

Material	Typical carbon content (%)	Weight (g)
Wood	50	4–20
Charcoal	70	3.5–15.0
Dry peat	50	4–25
Wet peat	5	40–200
Humus	0–5	120–1000
Bone	0–30	50–500
Carbonate	12	15–60

Note: The weight ranges are quite wide since the quality of the sample will have a bearing on the amount of carbon remaining after pretreatment and the measurement device will have a bearing on the amount of sample required, for example, small versus large GPC (see Table 3).

solid-source counting techniques, originally developed by Libby (and coworkers), the inventor of the ^{14}C -dating method (Libby, 1952).

In their screen wall counter (Anderson et al., 1951), background reduction was achieved using a 20-cm thick steel plate as passive shielding while a ring of Geiger–Müller (GM) counters arranged around the counter and operated in anticoincidence was used as an active guard. The original system required about 8.5 g carbon per sample, spread over an area of 400 cm². Although the background could be reduced to an acceptable 4.5 counts per minute (cpm), efficiency was low (approximately 5%) because of high self-absorption, and this defined the upper dating range at <25 000 years before present (BP – the time unit for reporting ^{14}C ages; see section ‘Age Calculation’). Therefore, the method was soon abandoned in favor of either LSC or GPC. Figure 1 illustrates the basic sample preparation steps for AMS, LSC, and GPC.

Liquid Scintillation Counting

Instrumentation

It has been known for over half a century that certain aromatic compounds (fluors or scintillants) can convert the absorbed energy from nuclear radiation into photons of light. In LSC, photomultiplier tubes (PMTs) are employed to convert the weak light output into electrical pulses (Figure 2). Light impinging on the photocathode causes the emission of photoelectrons, which are accelerated toward the PMT anode, but before reaching it, they impinge on a series of dynodes, each of

Figure 1 Main steps involved in preparing samples for ^{14}C dating by accelerator mass spectrometric analysis, liquid scintillation counting, and gas proportional counting.

which causes an electron gain such that there is an overall gain of 10^7 – 10^{10} at the anode.

A major problem with early LSC designs employing a single PMT was its thermionic noise (dark current), which constituted the majority of the instrument background. Virtually all modern day scintillation counters are based on the design of Hiebert and Watts (1953) which employs: (i) two diametrically

Figure 2 Schematic representation of a photomultiplier tube indicating photons impinging on the photocathode and the electron gain at each dynode.

opposed PMTs with the sample vial situated between them, (ii) fast coincidence circuitry (20 ns resolving time) to differentiate between decay events occurring in the sample vial (mainly coincident) and random thermionic noise, and (iii) summation circuitry to sum the individual PMT pulses (Figure 3).

Between the 1950s and 1980s, LSC advances were mainly modifications to existing instrumentation and included:

- Incorporation of cosmic guard detectors.
- Increasing the passive shielding.
- Reducing the PMT voltage.
- Masking PMTs or vials to minimize PMT crosstalk (light-dark current).

Low-background materials for vial (quartz or Teflon™) and vial holder (e.g., delrin) construction also brought about significant background reductions.

In the 1980s, the instrument manufacturers began to realize the potential versatility of the LSC for modern environmental analysis and combined a range of background reduction features with modern microprocessor and multichannel analyzer (MCA) technology, making the technique truly spectrometric. Thus, many modern LSCs used for ^{14}C dating contain one or more of the following background reduction features.

Enhanced passive shielding

The normal 5 cm thickness of lead was increased substantially (e.g., Figure 4) to a minimum of 10 cm; with the inclusion of cadmium and copper linings, this has the following effects on the background:

- It reduces the background from environmental γ photons associated with building and instrument construction materials.
- It reduces the 'soft' cosmic muon component.

Figure 3 Schematic diagram of a liquid scintillation counter indicating the diametrically opposed photomultiplier tube (PMT), coincidence and summation circuits, and other electronic units.

Figure 4 Schematic representation of the Quantulus liquid scintillation counting illustrating the enhanced passive shielding, guard detector (liquid scintillant), and anticoincidence circuitry. MCA, multichannel analyzer; PMT, photomultiplier tube.

- The cadmium and copper linings absorb secondary X-rays and thermal neutrons.

However, an anticoincidence shield (active guard detector) is required to reduce the high-energy γ photon and hard cosmic ray components.

Anticoincidence shielding

An anticoincidence shield typically consists of a volume of scintillating material that surrounds the sample detector assembly and its PMTs (Figure 4). The shield has its own PMTs, operating in anticoincidence with the sample PMTs to reject events detected simultaneously by the guard and sample PMTs, and events detected only by the guard (e.g., Kojola et al., 1984). The guard will reject much of the residual environmental γ radiation, the soft cosmic component, and the harder cosmic muon flux.

Pulse discrimination electronics

As an alternative or in addition to the more traditional approach of enhanced passive shielding and an anticoincidence shield, some manufacturers employ circuitry that distinguishes true β -events from background events on the basis of differences in pulse shapes. The different forms of pulse discrimination electronics include the following:

- Integration of the delayed component of each pulse and comparison with the total pulse integral to produce an

Figure 5 Comparison of pulse shapes from a nonquenchable background event and a true β -event. PMT, photomultiplier tube.

amplitude-independent parameter that relates to the pulse shape (Kaiholo, 1991) or

- A comparison of the number of after-pulses from different events (Figure 5): the unquenchable component of background is the result of low photon yield Cerenkov events consisting of a prompt component followed by a significant delayed component, comprising a burst of after-pulses. In contrast, fewer after-pulses will follow the prompt pulses from ^{14}C β -events. Valenta (1987) designed circuitry to discriminate unquenchable background events from true β -events on the basis of the number of after-pulses that follow the prompt pulse, relative to the amplitude of this prompt pulse.

A further technique compares the ratio of the pulse amplitudes (as opposed to pulse shapes) produced by the two PMTs (Kaiholo, 1991) as a discrimination criterion since photons produced in the cocktail from a radioactive decay event are distributed in a relatively even manner so that the number impinging on the photocathode of each PMT will be similar. Therefore, the pulse amplitude ratios will vary around unity. In contrast, photons produced in the vial wall or in the PMTs will show greater variation and can be discriminated out.

Quasi-active guard detector

The pulse-shape analysis features described above can also be used in conjunction with a quasi-active guard detector, so called because it has no PMTs. It consists of a modified detector assembly, typically constructed from bismuth germanate ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$ or BGO) or a long fluorescence lifetime scintillating plastic. The guard surrounds the sample vial and is also optically coupled to the face of each PMT. The BGO or the slow

Table 2 Effect of various background reduction features on LSC performance

fluor in the plastic modifies background pulses making them much longer in duration than true β -events and this aids background discrimination. With plastic guards, a secondary fluor must be used to avoid overlap of the emission spectrum of the primary fluor with the absorption spectrum of the guard.

Table 2 gives performance data for (i) a standard LSC without background reduction features and (ii) a range of modern LSCs.

Sample Analysis

Benzene synthesis

In addition to instrumentation requirements, successful ^{14}C analysis depends critically on sample conversion into a suitable chemical form for counting. C_6H_6 is now almost exclusively used as the preferred chemical form for LSC (Figure 1). Its synthesis involves the following steps:

1. Sample conversion to CO_2 and subsequent purification. (After CO_2 purification, a small subsample is removed for $\delta^{13}\text{C}$ measurement to enable a fractionation correction to be made.)
2. Conversion of CO_2 to lithium carbide by reaction with molten lithium under vacuum.
3. Addition of water to the cooled carbide to generate C_2H_2 .
4. Cyclotrimerization of the C_2H_2 to C_6H_6 using a chromium- or vanadium-based catalyst.

Counter setup

Optimized LSC performance requires a counting window that maximizes the figure of merit, E^2/B (where E =efficiency and B =background count rate). This should be set up such that the lower discriminator excludes potential hydrogen-3 (^3H) events and the upper discriminator is set close to the sample ^{14}C spectrum endpoint. Using a modern computer-based MCA and a simple Basic program, it is possible to determine such an optimum window. Normally, a window will be selected which is both close to the maximum E^2/B and in which minimal changes in counting efficiency accompany any changes in quenching (a type of balance point counting).

Sample quenching

Small variations in C_6H_6 counting efficiency occur due to both impurities in the synthesized C_6H_6 and dissolved oxygen. These interfere with the conversion of β -particle energy to photons of light, that is, they cause quenching. Reduced light output results in the production of smaller PMT anode pulses and hence a shift in the β -spectrum to lower energies with a consequent loss in efficiency. To compensate for variable efficiency, a quench curve is produced in which a number of high, known-activity ^{14}C standards are counted in an identical counting geometry to samples (same vials, C_6H_6 weight, etc.) but with increasing amounts of a quenching agent added. Counting efficiency in the optimum window is then plotted against a quench indicating parameter (QIP). This QIP is derived from the spectrum of a γ photon-emitting external standard that is housed in a small shield within the LSC and moved (mechanically or pneumatically) to a position in close proximity to the scintillation vial on request. The γ photons from the standard cause Compton electron production in the vial. These electrons are subject to the same quenching as the ^{14}C β -particles and so the changes in the ^{14}C spectrum are mirrored by changes in the external standard spectrum. The QIP is therefore a measure of the degree of quenching of the external standard spectrum. All counting efficiencies can be normalized to the same value as the least quenched standard by applying a quench factor (QF) derived from the graph of efficiency versus QIP. All samples are then counted and the QIP values noted. These QIP values are used as above to determine a QF, which is applied to the net count rate of each sample.

Counting procedure

Most laboratories store the synthesized C_6H_6 for a minimum of 3 weeks to allow any radon-222 (^{222}Rn ; a decay product of uranium-238 (^{238}U) with a half-life of 3.8 days) contained in the sample to decay, otherwise the α -particles from the ^{222}Rn and the α - and β -particles from its short-lived daughters cause

an increased count rate in the ^{14}C counting window. Then, a fixed weight of sample C_6H_6 is added to a suitable vial containing the fluor(s). Most ^{14}C -dating laboratories use only a primary fluor at relatively high concentrations (12–15 mg g^{-1} C_6H_6). A primary (typically butyl-PBD) and a secondary fluor (bis-MSB) are recommended for modern PerkinElmer (Packard) TriCarb instruments that employ nonprogrammable pulse-shape analysis (called TR-LSC). The bis-MSB is used to enhance pulse-shape discrimination by suppressing after-pulsing in ^{14}C events (Cook and Anderson, 1992).

Most laboratories that use borosilicate vials will operate a quasi-simultaneous batch counting approach in which a batch of samples is cycled many times through the instrument, each sample counting for a relatively short time in each cycle to minimize the bias on any single vial caused by background changes. A typical batch would consist of about 20–30 vials and would include:

1. Background standards in the form of scintillation-grade C_6H_6 and C_6H_6 synthesized from infinite age (with respect to ^{14}C) material such as interglacial wood, geological age carbonate, anthracite, etc.
2. Modern reference standards, that is, C_6H_6 synthesized from the internationally recognized standard SRM-4990C (Oxalic acid II) (or SRM 4990 Oxalic acid I). Their activities can be related to the equilibrium living activity of an organism.
3. C_6H_6 synthesized from samples of an unknown age.
4. C_6H_6 synthesized from samples that have an internationally agreed consensus age.
5. A high-activity ^{14}C - C_6H_6 standard to monitor counter stability.
6. A high-activity ^3H - C_6H_6 standard to monitor spill of ^3H counts into the ^{14}C energy region.

Figure 6 illustrates the layout of a typical batch of samples in an LSC, with a background standard followed by a modern reference standard and several unknown age samples. This sequence is repeated several times with other standards at the end of the batch.

Figure 6 Layout of a typical batch of vials containing benzene for quasi-simultaneous batch counting where B, background (i.e., ^{14}C -free sample); M, modern reference standard (typically Oxalic acid II); S, unknown age sample; K, known age sample; ^{14}C , high-activity ^{14}C standard; and ^3H , high-activity ^3H standard.

After a number of cycles (e.g., 40 of 50 min counts) several checks will be undertaken of LSC stability and then (i) net count rates for modern reference standards, known age standards and unknown age samples will be determined from the gross count rates by subtracting a mean background count rate and (ii) QFs for individual standards and samples will be determined. These data will then be used to calculate ^{14}C ages (see section 'Radiometric ^{14}C Age and Error Calculations').

Modern low-background LSCs have been used to date small samples, for example, Haas and Trigg (1991) dated samples in the range 200–600 mg, however, a major drawback is the extended counting times required. This approach has now largely been abandoned in favor of AMS. In contrast, Pearson (1979) used large samples (approximately 13 g C_6H_6) to produce high-precision measurements (± 20 years BP). He used a standard LSC without background reduction features but optimized all aspects of the method and introduced a number of correction factors for the counting process. Much of his high-precision LSC work, together with the GPC work of Minze Stuiver, was on producing the high-precision dendrochronological calibration curve (e.g., Pearson and Stuiver, 1993; Stuiver and Pearson, 1993).

Gas Proportional Counting

Instrumentation

Gas counters were developed during the beginning of the twentieth century, long before the advent of radiocarbon dating, and consist basically of a cylindrical volume with a thin wire stretched along the axis (Figure 7).

The volume contains a gas, and an electrical field is applied between the cylinder and the wire. The polarity is chosen so that the central wire is positive (anode) with respect to the outer cylinder (cathode). The electric field is at a maximum at the anode wire and decreases rapidly toward the cathode; using thin wires, very high field values are achieved close to the anode. The counting gas (originally argon/alcohol) will be ionized by particles or electromagnetic radiation and the electrons produced will drift toward the anode because of the electric field. Very close to the wire, the field becomes so strong that multiplication starts (typically $>10^6$) and an avalanche of electrons develops. The charge detected at the wire depends

strongly on the applied voltage and in the so-called proportional region this charge (after multiplication) is proportional to the energy of the decay event. This is the regime for GPC. For more details the reader is referred to Friedlander et al. (1981) and Watt and Ramsden (1964).

The practical solution to the problems of low activities and low energies described in the section 'Introduction' was developed in the 1950s, and involved the employment of both GPC counters (for ^{14}C detection) and GM counters (for cosmic ray background reduction), a passive shield, and the use of a gaseous form of carbon (synthesized from the sample material) as the counting gas. In normal operation, the radioactive source is outside the GPC; however, the low-energy β -particles emitted by ^{14}C cannot penetrate the counter walls. Using carbon in the gaseous form as the counting gas solved this problem. Thus, the counting gas is also the sample. CO_2 is the most commonly used counting gas (Mook, 1983). The emphasis on CO_2 is caused by the fact that (i) CO_2 is the primary gas that has to be produced in all cases, after sample pretreatment, via acid hydrolysis, wet oxidation, or combustion; (ii) the cryogenic properties of CO_2 facilitate handling and thus minimize contamination; and (iii) all laboratories involved in high-precision work (like calibration of the ^{14}C timescale) use CO_2 . Some laboratories prefer the use of the other gases in order to avoid the high purity requirements for CO_2 as a counting gas.

GPC counters

Basically, two types of GPC have been developed for CO_2 gas counting: quartz tubes coated with a thin (typically $0.01\ \mu\text{m}$) conductive gold layer acting as the cathode (e.g., de Vries et al., 1959), and copper tubes (e.g., Tans and Mook, 1978). In both cases, great care has to be taken that the construction materials are free from radioactive contamination.

Key parameters affecting low-level $^{14}\text{CO}_2$ counting are gas pressure, anode voltage, and gas multiplication (Kromer and Münnich, 1992).

The gas pressure determines the precision of the ^{14}C measurement. For example, a statistical precision of 0.1% corresponds to 10^6 counts. If this needs to be measured in a 1-day counting period, the counter has to contain 2 mol of carbon, equivalent to 50 l of CO_2 gas at National Toxicology Program (NTP).

In addition, the CO_2 pressure affects background and the demands on gas purity. Because problems with electrical insulation and impurity sensitivity pose limits to the counter diameter, Tans and Mook (1978) developed a system of seven parallel-connected (sub)counters, operating with CO_2 at pressures up to 6 bar. All seven are made of quartz and can operate at the same high voltage, close to 7 kV. The anode wires are stainless steel with a diameter of $25\ \mu\text{m}$. These numbers represent the ideal design parameters and in practice, the counters operate at pressures around 3 bar.

Special counters

Special GPC designs include multiwire counters and mini-counters. The sensitivity in GPC can be improved by increasing the size of the counter and by increasing the gas pressure; however, increasing the diameter and/or the pressure would require higher voltages to be applied across the counter. This

Figure 7 Schematic representation of a gas proportional counter.

can be avoided by dividing the sensitive volume into several wall-less counter elements, the so-called multielement counter (Povinec, 1992); however, in practice their operation is rather complex.

Mini-counters comprise an array of counters designed for small samples (typically 10–100 mg C), inside a single anticoincidence shield (Oulet et al., 1986). Since ^{14}C dating requires a precision of 0.5% or better, counting times are long (many days) and this puts stringent constraints on the stability of the counting system. Again, the introduction of AMS made the mini-counters more or less obsolete for practical dating purposes.

Passive shielding

The purpose is the same as in LSC although shields for GPC can be more complex in design. A typical counter shield is shown in Figure 8. Iron is used to absorb the γ radiation from the

Figure 8 Typical passive and active shield assembly for gas proportional counters.

surroundings (potassium-40 (^{40}K) in concrete, etc.) and the nucleon component in the cosmic radiation. Neutrons are moderated to thermal energies by paraffin wax and subsequently absorbed by boron. The innermost shield, between the GM counters and the GPC, consists of 'old' (=low radio-activity) lead. Passive shielding reduces the cosmic ray background by about 10%.

Anticoincidence shielding

In most setups, a ring of GM counters connected in parallel surrounds the GPC. These operate in anticoincidence with the GPC, thereby acting as an active shield to register the cosmic ray background radiation. This active shield reduces the cosmic ray background by about 90%.

Electronics

A typical schematic overview of a measuring setup is shown in Figure 9. Each set of GPC and GM ring is connected to a controller unit, which includes adjustable discriminators (low, medium, and high), the settings of which depend on whether the detected pulse is selected as an α -particle (from ^{222}Rn), meson (cosmic ray particle), β -particle (from ^{14}C), or purity count. A separate controller collects external parameters such as barometric pressure, and counter gas pressure and temperature of each individual counter.

Sample Analysis

Counting gas

As with LSC, the advantages of the gas counting technique over solid-source counters are the high detection efficiency and 4π geometry, while in addition, the problems of cross-contamination using solid graphite can be avoided. The choice of gas is made with a view to chemistry (sample treatment) and purification. CO_2 , CH_4 , C_2H_6 , and C_2H_2 fulfill these requirements and are commonly used by ^{14}C laboratories. de Vries (1956) developed the CO_2 method, which is the simplest for

Figure 9 Typical schematic overview of a gas proportional counting setup. GM, Geiger-Müller; GPC, gas proportional counting.

gas production from sample materials; however, it is very sensitive to small amounts of impurities such as oxygen: concentrations greater than $1:10^6$ are sufficient to reduce the gas gain as electrons originating from ^{14}C decay and drifting to the anode of the GPC may become attached to the electronegative impurities in the CO_2 gas.

CO₂ preparation

The sample is combusted to CO_2 in a stream of oxygen (O_2), typically over several hours, to ensure complete combustion (Figure 10). Next, a copper oxide (CuO) furnace at 800°C oxidizes carbon monoxide (CO) to CO_2 while silver (Ag) wool at 450°C removes any halides present, and finally, potassium permanganate (KMnO_4) solution removes sulfides. Water (H_2O) is trapped cryogenically in CO_2 /methanol (CH_3OH) at -78°C and the final product, CO_2 , is frozen in liquid N_2 . Finally, the CO_2 is passed over Cu at 500°C to oxidize oxides of nitrogen. The CO_2 (typically a few liters) is then stored in a steel or glass container, from which it can be transferred

Figure 10 Sample undergoing combustion in a stream of oxygen.

Figure 11 The Groningen gas proportional counter facility.

cryogenically back and forth to the GPC. As with C_6H_6 , the CO_2 is stored for about 1 month to allow any ^{222}Rn to decay.

A few milliliters of CO_2 are removed for $\delta^{13}\text{C}$ measurement, necessary for isotopic fractionation correction. The Groningen GPC facility is shown in Figure 11.

Counting procedure

Counting times depend on parameters like precision required or age of the sample, but are typically 24 h per sample. Backgrounds and standards are measured monthly but for a few days. Table 3 illustrates the limits of detection, etc., of several GPC systems in use in Groningen.

For GPC, high-precision (defined as 0.2% or better) measurements are possible using large counters like Groningen counter number 9. As with LSC, such precision is needed for calibration of the radiocarbon timescale (Pearson and Stuiver, 1993; Stuiver and Pearson, 1993) and for dating projects where high temporal resolution is required (e.g., van der Plicht and Bruins, 2005). The latter may serve as an example project for stringent quality control.

Activity calculations

The total number of counts N during a counting time t_c is:

$$N(AB)t_c$$

where A represents the net ^{14}C count rate, and B the background count rate. However, this simple relationship requires corrections for barometric pressure and CO_2 purity. Higher barometric pressure means a greater thickness and mass of atmosphere, which acts as a shield against the cosmic ray flux. In routine CO_2 counter operation, the counter itself determines the gas purity. At fixed counting conditions (such as voltage and pressure), electronegative impurities result in a decrease in pulse height, which causes a shift of the counter plateau towards higher voltages. A similar shift occurs in the meson characteristic curve, which is measurable by the decrease in the count rate at the steep part of the curve (Figure 12). The decrease in meson count rate can be converted to that in the β count rate through a comparison of both slopes (Brenninkmeijer and Mook, 1979).

Radiometric ^{14}C Age and Error Calculations

Age Calculation

For LSC: once the net count rates per gram of C_6H_6 have been determined for oxalic acid standards, known age standards and unknown age samples, an activity correction for quenching is applied. Similarly, for GPC: once the net count rates per unit mass of CO_2 have been determined, activity corrections for gas purity and atmospheric pressure are applied. Following these procedures, activities are further corrected for fractionation using a fractionation factor (FF) calculated using the $\delta^{13}\text{C}$ value. This correction is common to LSC and GPC. Fractionation arises from differential uptake of isotopes by physical and/or chemical processes. These processes, both in nature and in the laboratory (during sample preparation), are dependent on mass. Therefore, fractionation changes the ^{14}C content of the sample (relative to the ^{12}C content) and consequently the

Table 3 Performance characteristics of some of the large and small Groningen gas proportional counters

Counter	Number of counters	Volume (ml)	Pressure (mbar)	Minimum weight of carbon (g)	Maximum measurable age (years BP)	A_0 (cpm) ^a	Background (cpm)
9	7	6840	2907	12.5	58000	118.3	13.9

**Figure 12** Shift in the β -curve and accompanying meson curve caused by the presence of electronegative impurities in the counting gas.

^{14}C age, if a correction factor is not applied. Correction can take place because the ^{13}C isotope is also fractionated (relative to the ^{12}C) and because the change in the $^{13}\text{C}/^{12}\text{C}$ isotopic ratio is proportional to the change in the $^{14}\text{C}/^{12}\text{C}$ ratio. Therefore, the FF is effectively a normalization factor that corrects the different ^{14}C activities of contemporaneous samples using their $\delta^{13}\text{C}$ values. The $\delta^{13}\text{C}$ value of -25% (0.025) in the equations is the theoretical value for wood and the factor of 2 in the equations takes into account the fact that $^{14}\text{C}/^{12}\text{C}$ fractionation is twice that of $^{13}\text{C}/^{12}\text{C}$.

For unknown age samples and Oxalic acid II standards,

$$\text{FF} = 1 - [2(0.025 + ^{13}\text{C})]$$

For Oxalic acid I standards it is:

$$\text{FF} = 1 - [2(0.019 + ^{13}\text{C})]$$

Therefore, the normalized sample activity is:

$$A_{\text{SN}} = A_s [1 - [2(0.025 + ^{13}\text{C})]]$$

where A_s is the measured sample activity uncorrected for fractionation and A_{SN} is the normalized sample activity.

Similarly, the normalized activity for Oxalic acid II is

$$A_{\text{ON}} = 0.7459 \times A_{\text{OXII}} \{1 - [2(0.025 + ^{13}\text{C}_{\text{OXII}})]\}$$

while the normalized activity for Oxalic acid I is

$$A_{\text{ON}} = 0.95 \times A_{\text{OXI}} \{1 - [2(0.019 + ^{13}\text{C}_{\text{OXI}})]\}$$

where A_{OX} is the measured oxalic acid activity and A_{ON} is the normalized activity.

The A_{ON} activity was originally based on the age corrected activity of tree rings growing during AD 1890 and in equilibrium with the AD 1890 atmosphere. AD 1890 is the last time when the ^{14}C record was not significantly perturbed by anthropogenic influences. The first primary reference standard (Oxalic acid I) was produced in 1957 and has an internationally accepted reference value of: $0.95 \times$ the activity of Oxalic acid I, in AD 1950, normalized to a $\delta^{13}\text{C}$ value of -19% (with respect to Vienna Pee Dee Belemnite (VPDB)) = activity of AD 1890 wood. The measurements were not made in AD 1950 but this was deemed to be an appropriate reference year. Therefore, when a sample is dated, its age is always quoted in years BP where 'present' is AD 1950. Since the samples and oxalic acid standards have been decaying at the same rate post-1950, there is no need for decay corrections. By 1978, supplies of Oxalic acid I were practically exhausted and Oxalic acid II, synthesized from sugar beet grown in 1977, was introduced in 1980 (Mann, 1983): $0.7459 \times$ the specific activity of Oxalic acid II normalized to a $\delta^{13}\text{C}$ value of -25% equates to the Oxalic acid I reference value. The 0.95 and 0.7459 factors take into account the fact that the oxalic acid standards were produced from materials that grew during the nuclear era.

From the above, the fraction modern (F) of the samples is calculated using Oxalic acid I as follows:

$$F = \frac{A_s \{1 - [2(0.025 + ^{13}\text{C})]\}}{0.95 \times A_{\text{OXI}} \{1 - [2(0.019 + ^{13}\text{C}_{\text{OXI}})]\}} = \frac{A_{\text{SN}}}{A_{\text{ON}}}$$

Similarly, using Oxalic acid II:

$$F = \frac{A_s \{1 - [2(0.025 + ^{13}\text{C})]\}}{0.7459 \times A_{\text{OXII}} \{1 - [2(0.025 + ^{13}\text{C}_{\text{OXII}})]\}} = \frac{A_{\text{SN}}}{A_{\text{ON}}}$$

This is the activity ratio ^{14}a (also called 'percent modern'; Mook and van der Plicht, 1999).

From this, the radiocarbon age (t) can be calculated as follows:

$$t = \frac{1}{\lambda} \ln \left[\frac{1}{F} \right] = 8033 \ln \left[\frac{1}{F} \right]$$

where t = age in years BP since the death of the organism and λ = decay constant for ^{14}C ($\ln 2/5568$). The half-life of 5568 years is the original half-life used by Libby and is used by convention in age calculations and the definition of 'BP.'

Stuiver and Polach (1977) and Mook and van der Plicht (1999) provide a detailed discussion of radiocarbon conventions and nomenclature.

Error Calculation

Because radioactive decay is a random process, a repeated measurement of the same sample under identical conditions will not give the same result. The uncertainty in a measured activity is given by the standard deviation (σ). The standard deviation in a total number of counts N during a counting time t_c is $\sqrt{N}$ (Poisson error). Radiocarbon laboratories do not have a standardized method of determining errors on age measurements because of the variations in counting procedures but at a minimum, the error should include Poisson errors from the sample, Oxalic acid standard(s) and background count rates, together with errors on the relevant correction factors. Furthermore, the overall error is normally subject to a minimum value based on the standard deviation of a set of replicate analyses of a bulk sample.

Typical measurement precision for ^{14}C laboratories is 0.5% or better and this applies to all three detection techniques, AMS, LSC, and GPC.

An indepth discussion of error calculations and quality assurance issues can be found in this encyclopedia.

Accelerator Mass Spectrometry Fundamentals

Over the last nearly three decades, accelerator mass spectrometry (AMS) has developed from a curiosity to become by far the most common method of radiocarbon dating. The technique developed from the need for more sensitivity and smaller sample sizes than could be achieved by decay counting (Cook and van der Plicht, this volume). The first reports of the use of an accelerator combined with a mass spectrometer system were reported in 1977 (see Tuniz et al., 1998 for the historical discussion). AMS has become one of the most important tools in the geochronologist's arsenal to try to determine the age of material. For radiocarbon, precise measurements are needed to determine an age. For details of the principles of radiocarbon dating, the reader is referred to the section of van der Plicht (this volume).

A fundamental difference between radionuclide measurement using AMS differs from the decay counting methods (Cook and van der Plicht, this volume) is the number of atoms of the radionuclide in the sample is measured directly, instead of waiting for individual radioactive decay events. For radiocarbon (^{14}C) dating, this makes the technique 1000 to 10 000 times more sensitive than counting of the radioactive decay. AMS also has important applications for other longer lived radionuclides.

It is easy to understand the usefulness of AMS by looking at the radioactive decay equation

$$dN/dt = -\lambda N$$

Here, the number of atoms of ^{14}C , N , is related directly to the rate of radioactive decay (dN/dt) through the decay constant, λ . So, the decay rate is very slow; for 1 g of modern carbon, the decay rate is 13.59 dpm g^{-1} . In AMS, one typically measures a sample of 0.5 mg C, and over 120 000 atoms can be counted from a modern sample. If one takes a counting rate of 120 000 atoms in 1080s, or 111 counts/second – from 0.5 mg of carbon, then this translates to $111 \times 60/0.0005 = 1.33 \times 10^7$ cpm g^{-1} , a difference compared to decay counting of over a million.

The extreme sensitivity is achieved by accelerating sample atoms as ions to high energies using a particle accelerator and using nuclear particle detection techniques (Tuniz et al., 1998). The first purpose built machines for AMS radiocarbon dating relied on the design of Purser et al. (1980) or the redesign of existing Van de Graaff accelerator systems, some of which

continue to provide valuable data. Early machines dedicated to AMS radiocarbon were installed at the Universities of Oxford, Arizona, Toronto, and Nagoya in the early 1980s. Newer designs resulted from competition after the expiry of the original patent (see Purser et al., 1980), and this equipment is currently commercially available from National Electrostatics Corporation (NEC; Middleton, Wisconsin, USA) and High Voltage Engineering Europa (Amersfoort, the Netherlands). The field has grown continuously since that time, with over 70 purpose built AMS machines operating in 2010, and orders for a number of new machines are pending.

A picture of the 3 MV AMS at the University of Arizona is shown in Figure 1 and later a diagram of the design of the 3 MV AMS machine (based on an NEC accelerator) is shown in Figure 2.

Today, high external precision of about $\pm 0.35\%$ in ^{14}C content, or ± 30 years in uncalibrated radiocarbon age is easily achieved on a single 0.5-mg-sized sample target in 20 min of measurement time. Samples as small as 100 μg or less have been successfully dated and even smaller samples (~ 10 – $20 \mu\text{g}$) have been measured for special experiments, with reduced precision due to limited time available to measure the sample. With longer counting times or using multiple target measurements to reduce error, one can achieve better than ± 20 years in radiocarbon age.

The AMS method has also greatly improved the measurements of longer lived radionuclides such as ^{26}Al , ^{10}Be , ^{36}Cl , ^{41}Ca , and ^{129}I , which were very difficult to measure using counting techniques; measurements of small amount of these radionuclides is now routine (Fifield, 1999; Jull and Burr, 2006; Tuniz et al., 1998). Many geochronological applications using AMS radiocarbon and other AMS-based methods are discussed elsewhere in this encyclopedia.

An Example of AMS Operation

In order to demonstrate how the AMS operations, we will look at an example, from an AMS system at the University of Arizona. An AMS system at Arizona consists of the following basic components and sequence of processes. There are many good descriptions of the methodology of AMS (Fifield 1999; Jull and Burr 2006; Jull et al., 2003; Kutschera 2005; Synal and Wacker, 2010; Tuniz et al., 1998), so we refer the reader to these publications for detailed operational information.

Figure 1 Photograph of the University of Arizona 3 MV accelerator mass spectrometer, built by National Electrostatics Corporation.

Figure 2 Diagram of the operation of the 3 MV AMS. The major elements of the machine are shown. The ion source generates $50 \mu\text{A}$ or more of C^- , these ions are accelerated and passed through the low-energy magnet, where the first separation by mass occurs. Molecule ions are destroyed, once the ions are further accelerated to 2.5 MV and passed through the stripping canal (**Figure 3(e)**).

The quantity produced by the AMS measurement is usually expressed as the fraction of modern carbon (F) which can be related to the equations shown by van der Plicht (2005) earlier in this volume. Calculations are discussed later in this article.

In this discussion, one refers to **Figure 2**, which shows a diagram of the 3 MV NEC system at Arizona. This figure summarizes the major design elements of the system and also

operational conditions for ^{14}C . One can also look at some pictures of the various components.

1. The ion source (**Figure 3**) generates negative carbon ions ($20\text{--}60 \mu\text{A C}^-$) by Cs sputtering from a graphite target. A diagram of this process is shown in **Figure 4**. The graphite target must be prepared from the original sample material;

Figure 3 Source for the generation of C^- ions by sputtering of the graphite target.

Figure 4 Diagram of the ion-source operation.

the chemistry is discussed later. Good sample currents are 50–70 μA . At Arizona, one measures each target for 200 s, and the complete target wheel of 40 targets is rotated a total of six times, giving a total analysis time on one sample of about 20 min. Usually, one runs one wheel of 40 targets per day. In some laboratories, gas ion sources are under development, but these have not yet reached the reliability of the solid graphite source (Kim et al. 2002).

2. The injection magnet (Figure 5) performs the initial separation of the negative ions by mass. At this point, molecular ions such as hydrides of carbon (CH^-) are also present. N^- is unstable, so an important possible interference is removed. Mass 14 is measured most of the time and in our 3 MV Pelletron machine, masses 13 and 12 are pulsed rapidly through the machine for short intervals.
3. The accelerator (Figure 6), which generates a high voltage of 2.5 million volts (for ^{14}C measurements) and accelerates the C^- ions toward the central part of the machine, which is at high voltage and usually called the 'terminal.'
4. The terminal houses a gas canal known as the 'stripper.' The 2.5 million volt C^- ions enter this gas canal and

interact with a gas. The canal is differentially pumped, so that a high vacuum can be maintained in the accelerator tubes. Because they are moving so fast, they lose several electrons from their electron cloud and as a result become positively charged (see Figure 7 for a diagram of this process). Any molecules, such as CH^- are destroyed in this process. The positively charged ions are accelerated away from the positively charged terminal to the exit of the accelerator.

5. The ions exit the accelerator and are then separated by energy and charge, using the first of two electrostatic deflectors. This device deflects a beam of ions using an electrostatic field and a narrow defining exit slit. The 3^+ ions are selected.
6. The 3^+ ions are now passed through a large 90° magnet. When mass 12 or 13 is injected, these ion beams stop in Faraday cups after the high-energy magnet and the current is measured. If mass 14 is injected, the ^{14}C passes through a 77° electrostatic analyzer, shown in the earlier diagram (Figure 2), and then hits an energy-sensitive solid-state detector (Figure 8). A gas detector (Figure 9) is also used in some AMS machines and for other radionuclides. In the case of the surface-barrier detector, it has the property that it produces a pulse proportional in height to the energy of the ion, for every ion hitting the detector. A thin foil in front of the detector slows down the few $^{14}N^{3+}$ ions that make it through the machine. A similar process occurs in a gas detector, although we can get additional separation with this type of device. The number and energy of the ions are separated by computer, and the ^{14}C can be distinguished from any other ions which are counted. The count rate for a modern sample is around 120 counts per second. An example of the measurement for a counting spectrum is shown in Figure 10; this shows the low number of ^{14}N ions to the left of the ^{14}C .
7. The ratio of ^{14}C – ^{13}C current in the sample is compared to that of the standards. Appropriate corrections are made for the small natural variations of $^{13}C/^{12}C$ ratio and for the background. The radiocarbon age can now be calculated.

Chemical Preparation of Samples

An important aspect of AMS, like all radiocarbon dating, is to make sure that the samples which are studied have been cleaned of possible contaminations. Because of the small sample size, it is important that the sample is clean and all contaminants have been removed. Some basic procedures for AMS radiocarbon samples at Arizona were summarized by Jull et al. (2004):

1. Acid–base–acid (ABA) method for charcoal, wood, cellulose, plant material, animal tissue: After physical inspection, samples are cleaned with 1 N HCl acid, 0.1% NaOH, and 1 N HCl (ABA pretreatment), washed with distilled water, dried, and combusted at 900 °C with CuO. Hatté et al. (2001) discussed some modifications and potential problems with the ABA method.
2. Carbonates: In general, samples are etched with 100% H_3PO_4 to remove 50–85% of the carbonate, dried, and hydrolyzed with H_3PO_4 as discussed by Burr et al. (1992).
3. Selective combustion for sediments. After cleaning in 1 N HCl and drying, the sample is combusted at 400 °C in ~0.3 atm. oxygen gas (McGeheh et al. 2001).
4. Oxidative acid cleaning for old charcoal. A new method to handle old charcoal samples was developed by Bird et al. (1999). In this procedure, chromic acid is used to remove all except the most resistant charcoal in a sample. This is of particular interest for charcoal samples >20 ka.
5. Textiles, parchment, canvas, art works, and artifacts: The samples are given the ABA pretreatment and after washing and drying, they are Soxhlet extracted with hexane, then ethanol and finally methanol. After washing in distilled

water, and drying, they are combusted at 900 °C with CuO. Bruhn et al. (2001) proposed a more complex, six-stage cleaning procedure for art works.

Of course, for some specialized samples, other methods need to be developed for these applications.

After cleaning and combustion, samples are converted to graphite using a catalytic decomposition reaction, using an Fe catalyst and Zn as the reducing agent for the reaction $2\text{CO} \rightarrow \text{CO}_2 + \text{C}$.

Finally, the graphite powder is pressed into a target holder of Arizona design, which is now widely used in all NEC ion sources. The target material is pressed from both sides in a press-anvil arrangement.

Calculation of Results

Calculation and normalization to standards

The measurement of ^{14}C follows the procedures and calculations described in detail by Donahue et al. (1990) and further discussed by Burr and Jull (2009). McNichol et al. (2001) have reviewed the question of interlaboratory differences in calculations.

As discussed by Cook and van der Plicht (this volume), the result from any radiocarbon measurement needs to be expressed in the form:

$$F = A_{\text{SN}}/A_{1950\text{AD}}$$

where A_{SN} is the activity of ^{14}C in the sample compared to the value for 'modern carbon,' arbitrarily defined as the value of 1950 AD wood. All radiocarbon measurements are normalized to a common $^{13}\text{C}/^{12}\text{C}$ ratio quoted as $\delta^{13}\text{C}$ of -25‰ , to eliminate any effects of isotopic fractionation either in the sample or the measurement.

Because of depression of the ^{14}C signal due to fossil fuel burning, the value of AD 1950 material is taken to be:

$$A_{1950\text{AD}} = 0.95A_{\text{HOxI}}$$

where HOxI is the original Oxalic-I standard. Since that time, a second primary standard known as HOxII was developed by the US National Institute of Standards and Technology (NIST) as is designated as standard reference material SRM-4990C by NIST. This material can be related to HOxI as follows:

$$A_{1950\text{AD}} = 0.95A_{\text{HOxI}} = 0.7459A_{\text{HOxII}}$$

It is important to note that the value of A_{HOxI} was normalized to a $\delta^{13}\text{C}$ value of -19‰ instead of the $0.7459A_{\text{HOxII}}$ which was normalized to -25‰ .

Donahue et al. (1990) discussed the calculation of F from the raw AMS results, and this was also followed up by McNichol et al. (2001). Many AMS laboratories actually measure $^{14}\text{C}/^{12}\text{C}$ and not $^{14}\text{C}/^{13}\text{C}$ in this calculation; the reader is referred to these papers for details of the calculation and, in particular, the importance of the isotopic corrections.

Errors

Errors are calculated from the larger of the Poisson error (determined from $\sqrt{N}/N$) and the standard error of the individual measurements. Various laboratories use different methods to estimate the total error, but the best practice is to

take the larger of these two errors as the minimum error. Donahue et al. (1990) discussed the practice at Arizona, which is used in many laboratories. In this case, an additional error known as the 'machine random error' is added to the Poisson error before comparing this error to the estimate derived from the standard deviation of the individual measurements. Detailed error analysis considerations are also given in the section by Scott (this volume) and also by Burr and Jull (2010).

Blank corrections

During the processing of samples in the chemistry lab, it is impossible to avoid some small amount of contamination introduced either during the chemistry or conversion into graphite. The 'blank' in the machine itself is negligible. One can define a blank component, f , where:

$$f = F_{\text{B}}/F_{\text{std}}$$

where F_{B} is the fraction of modern carbon in the blank material itself; this is often assumed to be recent or modern carbon. However, other studies suggest one component of the blank may be an 'average' contamination from the last samples run on the line. Donahue et al. (1990) showed that the fraction of modern (F) for the sample can be expressed as:

$$F = F_{\text{m}}[1 - f\{1/F_{\text{m}} - 1\}]$$

where F_{m} is the value of the fraction modern measured for the sample, and F is the final corrected value.

New Trends: Smaller and Smaller Machines

Starting in the mid-1990s, there was a developing trend to make small AMS machines. This trend began about 1996 when a compact design (Hughey et al., 1997) was proposed and was followed by the development of an 0.5 MV machine of a different design by NEC in cooperation with ETH-Zürich (Suter et al., 1999).

The 0.5–1 MV 'Small' Tandem

As already mentioned, the first design for a <1 MV AMS was that of Hughey et al. (1997), who developed the instrument for biomedical work. About the same time, scientists at the ETH in Zurich (Suter et al., 1997) discussed the possibilities of a 0.5–1 MV AMS which would operate in the 1+ or 2+ charge state (as opposed to 3+, which the reader will recall, is used in the larger machine example given above). Suter et al. (2000) later reported on the design of a prototype 0.5 MV machine which would use the 1+ charge state. In this case, the design resulted in a compact machine of about 3–4 m on each side. Although the machine could operate in other than the 1+ charge state, due to transmission considerations most of the discussion on these small machines has involved the 1+ charge state.

Several 0.5 MV machines (Figure 11) are operational at eight facilities, located in Europe, the United States, and China. As noted in the next section, there are new designs going to even lower terminal voltages, perhaps as low as 200 kV, which would eliminate the need for a costly accelerator. One prototype design of this machine was constructed in

Zürich (Synal et al., 2005), and there are at least two additional machines of this type planned (see Synal et al., 2010).

However, there are a number of practical limitations to these very small machines. The control of the stripper gas pressure is delicate and essential. In the $1+$ charge state, molecular ions can exist. The assumption used for higher energy AMS operating conditions that the molecular ions are destroyed cannot be taken for granted at low energy. High stripper gas pressure is needed to remove molecular interferences. Southon et al. (2004) have also reported on the technical difficulties of these operating conditions.

200 kV Machines

Synal et al. (2005) and Synal and Wacker (2010) discussed the development of a 200 kV machine which eliminated both the accelerator tank and also the accelerator tubes. The device designed by Synal and coworkers consists of two gap lenses and a stripper tube and is called 'MICADAS' by the developers. The potential is generated by a 200 kV commercial power supply. The device, of course, must be placed in the mass spectrometer (which makes it much larger). Wacker et al.

(2010) report on routine operation of this new machine, with backgrounds similar to other AMS systems for chemical blanks (ca. $4\text{--}6 \times 10^{-15}$). They also estimated the contribution to the observed blanks from molecular interferences in the ion beam to about $2\text{--}3 \times 10^{-15}$ $^{14}\text{C}/^{12}\text{C}$. In 2010, machines are being constructed for a facility in Mannheim, Germany, and another in Debrecen, Hungary.

The 'Single Stage' AMS

Schroeder et al. (2004) of NEC (Middleton, Wisconsin, USA) reported on the design of another machine, which has since been installed at the University of Lund and included a 300 kV accelerator, also without any pressurized gas tank (Figure 6). This is described as 'single stage AMS', although it still actually has several stages. This device generates the 300 kV by floating the high-energy part of the machine at 300 kV with a commercial power supply, a section of accelerator tube in air provides the acceleration (see Figure 12). The stripper is then at ground potential, and the high-energy mass spectrometry is performed following the stripper without any further acceleration (see Figure 13). This interesting design apparently has similar

backgrounds to the 0.2–0.5 MV machines and is a new competitor to larger AMS machines for ^{14}C dating (Skog, 2010). These machines are operational at several commercial facilities in the United States for radiocarbon dating and radiocarbon tracer work applied to biomedical applications.

Errors and Uncertainties in Radiocarbon Dating

As an estimated carbon-14 (^{14}C) age, X , can be considered as a realization of a random process (due to the nature of radioactive decay), a conceptual model may be considered that states that there is a true but unknown ^{14}C age (often in statistical terminology called a parameter, written as μ), and that our estimated ^{14}C age can be modeled as a realization of a random variable with expected value equal to the true age and variance (or uncertainty) represented by a further unknown parameter, σ^2 . The commonly used probability model for the ^{14}C -dating process is the Gaussian or normal model, defined by the mean which equals the true but unknown ^{14}C age and the standard deviation or measure of uncertainty. This is frequently written as:

$$X \sim N(\mu, \sigma^2)$$

This uncertainty, or σ , is estimated in the error (standard deviation or σ) that is reported with a measured (estimated) ^{14}C age. It is typically based on counting statistics, but may also include components due to other laboratory corrections (e.g., error on fractionation correction). In recent years, there have been several publications where the use of a laboratory error multiplier has been introduced. Such an error multiplier captures sources of variation in the estimated ^{14}C age that are not accounted for in the quoted error.

The interpretation of a single measured ^{14}C age and its associated error is as follows: it is assumed that the measured ^{14}C age (an age estimate) is a realization of a random Gaussian process with a 'true but unknown ^{14}C age' and σ equal to the quoted error. The best estimate of the true ^{14}C age is the measured ^{14}C age, but the true value is highly (95%) likely to lie in the range:

$$\text{Estimated radiocarbon age} \pm 2 \times \text{quoted error}$$

Traceability

It is often important to be able to compare results from different laboratories or from the same laboratory at different times. This is, in many cases, achieved by establishing a chain of calibrations to primary, national, or international standards. Traceability may be demonstrated through comparison of measurement results on a certified reference material, or through using an accepted procedure. Frequently, numerous measurements are needed to define reference materials. This can be achieved as one result of proficiency trials for laboratories or laboratory round-robin/intercomparisons. For ^{14}C dating, the primary standard is 1890 wood, but the reference material most closely associated (and often called the primary standard) is oxalic acid (NBS OxI and NIST OxII). Additional secondary standards have also been developed, including IAEA C1–C6. Such secondary

standards (and further in-house reference materials) are measured on a routine basis, providing in-house quality assurance.

We can now investigate the basis for this conceptual model more carefully and also some of common measurement terms and descriptors that are used.

The Nature of Measurement and Uncertainty

All measurement is subject to uncertainty, which can be considered to have two components, one resulting from the analytical procedure and the other arising from the sample selection process. Every time an analytical measurement is made we get a different result. Typically we cannot analyze the entire sample, it must be selected from the environment it is found in, it may not be fully representative (there may be some heterogeneity, i.e., slightly different ^{14}C composition), so these sources of variation represent the uncertainty due to sampling. Often the emphasis in the laboratory is on the analytical uncertainty, since that is more readily quantified and modeled, but the uncertainty due to sampling is equally important although more difficult to quantify.

An estimate of analytical uncertainty is frequently attached to a measurement (age estimate) and reflects the range of values within which the true value is expected to lie. The uncertainty of a measurement describes the spread of values which might have been observed were the measurement repeated under *identical* conditions. In such a case, the repeat or replicate measurements will be different, and the spread of values is often characterized by a standard deviation, characterizing the precision of measurement but also the natural heterogeneity of the sample material in the field. To estimate the overall uncertainty, it may be necessary to estimate the individual components separately and then combine them using classical error propagation rules.

Measurement Uncertainty and Error

It is important to distinguish between uncertainty and error: error is a single value defined below, uncertainty takes the form of a range.

The error of a measurement, e , is the result of a measurement minus the true value and may include a random component and a systematic component. The error should always be reported with the measurement, and the overall uncertainty is then often expressed as the interval 'measurement $\pm e$ ' or 'measurement $\pm 2e$ '. The actual meaning of such ranges in terms of confidence or 'plausibility' depends on the stochastic model (or probability distribution) chosen to model the random error components. For a Gaussian model, the 1σ and 2σ intervals represent approximately 67% and 95% confidence, respectively.

Accuracy and Precision

Measurements are routinely described as being accurate and/or precise.

Accuracy is the closeness of agreement between a measurement and the true or reference value. If we imagine a series of measurements, each with the same true value, and if the average of the measurements does not equal (within error) the true value, then the measurement is said to be biased, where the bias is the difference between the *expected value* or average of a large series of measurements and the true value. Bias is usually considered to be systematic.

Precision is the closeness of agreement between a series of independent measurements obtained under identical conditions. Precision depends on the distribution of random errors, and is commonly computed as the standard deviation of the results. As the standard deviation increases, the precision decreases.

The archery targets in [Figure 1](#) represent accurate and precise, inaccurate and precise, accurate and imprecise, inaccurate and imprecise measurement from left to right, respectively. These and many other definitions can be found in the Royal Society of Chemistry, [Analytical Methods Committee \(AMC, 2003\)](#).

Uncertainty from Sampling

In the radiocarbon context, we can imagine that the ^{14}C measurement is made on a small component of the whole sample (e.g., a few grains from a silo), or that the archaeological sampling from a midden (which includes the materials to be dated), the security of the sampled materials in connection with the event being dated represent examples of uncertainty due to sampling. These examples also illustrate how difficult it is to quantify such uncertainty.

Stochastic Models

There are many stochastic models, but the most widely used (in ^{14}C dating) is the *Gaussian* or *normal probability model*.

The Gaussian probability model for a ^{14}C measurement X , is written as $X \sim N(\mu, \sigma^2)$, where μ is the expected value of X and σ is the standard deviation.

[Figure 2](#) shows 1000 estimated ages (true age 5000 years before present (BP)), the normal density function, with $\sigma = 30$ years.

Estimating μ and σ

The usual method of estimating μ and σ is based on a series of ^{14}C measurements on the same material made under identical

conditions. These measurements are denoted by $x_1, \dots, x_n$; the estimate of μ is the sample arithmetic average, and that of σ is s , the sample standard deviation. For the example above, the average of all 1000 results is 5001 years (so we could claim the measurement is unbiased) and the sample standard deviation is 31 years.

It is worth noting that the standard error of the mean (s.e.m.) is a measure of precision associated with the estimate of μ and is defined as

$$s/\sqrt{n}$$

thus distinguishing it from the standard deviation.

Estimating Uncertainty

The conventional radiocarbon age is reported as $t \pm \sigma_t$ years BP where σ_t represents the analytical uncertainty on the measurement, as estimated by the laboratory and typically quantified as a standard deviation.

The analytical estimate of σ_t is provided by the laboratory and will typically take into account the analytical uncertainties on the individual components which make up the conventional radiocarbon age.

The most basic form of the radiometric ^{14}C age equation is

$$t = \frac{1}{\lambda} \ln \left[\frac{A_0}{A_t} \right]$$

where t = sample age, which is the time that has elapsed since removal of the carbonaceous material from the carbon cycle (e.g., death of an organism); λ = decay constant, ($\ln 2/t_{1/2}$) where $t_{1/2} = 5568$ years (Libby half-life); A_t = the activity of the carbonaceous material t years after death as measured in the radiocarbon laboratory; and A_0 = 'modern equilibrium living activity' of the sample, again as measured in the radiocarbon laboratory.

A_0 and A_t are measured in the laboratory and both are corrected for fractionation effects. A_0 is measured using standard materials (ideally NIST oxalic acid), while A_t is the activity of the unknown sample. Both will also be adjusted/corrected for background using samples of 'infinite age.'

The analytical uncertainty for t will, therefore, include the uncertainty associated with modern standards, background samples, and fractionation. The actual analytical uncertainty on t (as a function of A_0 and A_t) is again derived through a fairly simple error propagation formula. However, it is also increasingly common that laboratories will take a long series of replicate measurements on a reference material and assess the standard deviation of the set. If the standard deviation is greater than the quoted errors on the individual estimated ages, then this would suggest an unaccounted source of variation and scientists may choose to quote the larger of the standard

Figure 1 Accuracy and precision.

Figure 2 A Gaussian ^{14}C model.

deviation of the set and the individual quoted error, or they may use an error multiplier approach.

How Do We Know Whether the Uncertainty Estimate Is Realistic?

Imagine a situation (known as *repeatability* conditions) in which independent measurements are made on identical samples in the same laboratory, using the same equipment. Such a situation might commonly arise using *reference materials* (typically available in bulk), such as a large quantity of known-age wood. A laboratory will routinely prepare a large number of such samples, each with a measured age and uncertainty. If the uncertainty estimate is realistic, then the between-sample variation should be explained fully by the uncertainties on the individual measurements. If this is not the case, it points to the fact that there are sources of error, contributing to the dispersion of results, which have not been taken into account.

Another measure of whether the uncertainty estimate is realistic can be obtained in a situation (known as *reproducibility* conditions), where independent measurements are obtained by the same method on identical samples in different laboratories. Such a set of conditions is commonly encountered in a *collaborative* or *proficiency trial*.

Interlaboratory Collaborative Trials

Proficiency testing is often used as a method for assessing the accuracy of laboratories in conducting particular measurements. It usually involves distributing 'identical' portions of the test material to each laboratory and analysis of the reported results, which helps each laboratory assess the accuracy of their measurement.

The radiocarbon community has devoted considerable care and effort to establishing and maintaining primary standards and reference materials and in the routine organization of laboratory intercomparisons or collaborative trials to verify

comparability of measurements. From such a series of collaborative trials, secondary standards or reference materials have been developed, including internationally recognized materials such as ANU sucrose (now also known as IAEA-C6), Chinese sucrose, and the IAEA C1–C6 series (Rozanski et al., 1992), augmented by additional oxalic acid samples (now IAEA C7 and C8; Le Clercq et al., 1998). The activity of these materials has been estimated from large numbers of measurements made by many laboratories. Recently, further natural materials from the Third and Fourth International Radiocarbon Intercomparisons (TIRI (Gulliksen and Scott, 1995) and FIRI (Bryant et al., 2000)) have been added to this list. The activities of these standards and reference materials span both the applied ^{14}C age range and the chemical composition range of typical samples. A summary of the intercomparisons organized within the ^{14}C -dating community can be found in Scott (2003). The results from the most recent intercomparisons have indicated that laboratories are generally providing accurate results, but pointed to variation in the results beyond that described by the quoted uncertainties. This provides some evidence that the quoted errors are underestimates of the laboratory precision for some laboratories. Figure 3 shows the results from FIRI (Scott, 2003) for one such reference material; each horizontal line represents the age $\pm 2\sigma$ quoted by a laboratory. Such a plot clearly shows the scatter in the results, but in addition further analysis can reveal evidence of laboratory bias (if present) and also assess the reliability of commonly quoted errors.

Figure 4 shows the difference (offset) between a laboratory's result and the 'true' age (or consensus value) evaluated from the FIRI intercomparison exercise (Scott, 2003). A small number of laboratories showed evidence of small but significant biases.

Calibration

Conventional ^{14}C ages are frequently converted to a calibrated age (on the historical timescale). In radiocarbon terms, this

Figure 3 Distribution plot of ages from a collaborative trial. BP, before present.

Figure 4 Estimation of bias from a collaborative trial. BP, before present.

means that we have a series of independently known-age samples (such as tree-rings), and in each sample, the ^{14}C age is estimated. The relationship between the estimated age and the true age is modeled and on the basis of the modeled relationship, a ^{14}C age can be calibrated to AD/BC timescale. This relationship has been shown to be of a complex, often nonlinear form, which has significant implications for the transformation of the measured ^{14}C age to a calibrated age

(IntCal04, 2004). The error in years BP on the estimated ^{14}C age must also undergo a transformation to give the corresponding error on the calendar-year scale. However, complexities arise due to the complex pattern of ^{14}C variations. The simplest complication is that although we often model the estimated ^{14}C age using a Gaussian model, once transformed or calibrated, the resulting stochastic model for the calibrated age is no longer Gaussian, it is often multimodal and no longer symmetric. The net effect is that often, the calibrated result has a greater uncertainty. The most commonly used calibration programs adopt a probabilistic approach, resulting in a calibrated-age probability distribution. Figure 5 shows a typical calibration of a single ^{14}C age. Commonly, probabilities are ranked and summed to find the 68.3% (1σ) and 95.4% (2σ) confidence intervals which can result in small, disjoint age ranges. The three most widely used calibration programs are Calib, BCal, and OxCal and an example using OxCal is shown in Figure 5. The main use of the calibration program is for terrestrial samples, although special calibration data sets are available for marine samples. All three programs are based on the same internationally accepted calibration data sets (IntCal04, 2004).

Variations in Atmospheric ^{14}C

J van der Plicht, University of Groningen, Groningen, The Netherlands

© 2013 Elsevier B.V. All rights reserved.

High-energy cosmic rays, mainly galactic and solar protons, impinge on the Earth's atmosphere. They produce nuclear reactions, with spallation products and neutrons as the main constituents. The high-energy neutrons slow down by scattering and finally reach thermal energies. These thermal neutrons have a large cross-section for a nuclear reaction with nitrogen, the main constituent of the atmosphere (78%): $^{14}\text{N}(n,p)^{14}\text{C}$. Other reactions, such as $^{16}\text{O}(p,3p)^{14}\text{C}$ and $^{16}\text{O}(n,2pn)^{14}\text{C}$, are much less abundant. The ^{14}C nuclei produced are oxidized with atmospheric oxygen to $^{14}\text{CO}_2$ and hence become part of the 'global carbon cycle.' Via photosynthesis in plants, ^{14}C enters the biosphere, which is in equilibrium with the atmosphere. The atmosphere and living terrestrial organisms thus contain ^{14}C in minute concentrations: the natural level is $^{14}\text{C}/^{12}\text{C} \approx 10^{-12}$ corresponding to a level of natural radioactivity of $\sim 225 \text{ Bq kgC}^{-1}$. Upon the death of the organism, the ^{14}C decays as a function of time with a half-life of 5730 years. Thus, by measuring the remaining amount of ^{14}C in fossil remains, the time of death can be established. This is the basis of the ^{14}C (radiocarbon) dating method.

The radiocarbon dating method is complicated by the fact that the natural ^{14}C content is not constant through time. The secular variations in atmospheric CO_2 were first discovered by de Vries (1958). These natural variations cause the ^{14}C timescale to differ from the real (calendar) timescale, resulting in the need for calibration. The ^{14}C dating method and timescale calibration are dealt with elsewhere in this encyclopedia. Here, atmospheric ^{14}C variations, both natural and anthropogenic, and their causes are discussed.

Production

Atmospheric ^{14}C is produced from the interaction of ^{14}N and secondary cosmic ray neutrons by the following exothermic nuclear reaction:

where the cross-section σ is expressed in barn(b): $1b = 10^{-24} \text{ cm}^2$.

The natural production of ^{14}C varies because the flux of primary cosmic ray protons (which produce a cascade of secondary particles, especially neutrons) is not constant. The galactic component of the proton flux is constant, but changes in the screening effect are the major cause of variations in atmospheric ^{14}C production. In the solar system, this screening occurs by the effects of the interplanetary magnetic field and in the vicinity of the Earth, it occurs by the geomagnetic field.

Near the Earth, cosmic ray particles encounter magnetic scattering from the geomagnetic field. This interaction varies greatly with latitude so that the production of ^{14}C is strongly latitude dependent. This is shown in Figure 1, in which the production of ^{14}C (number of nuclei/ cm^2/s) is plotted as a function of geomagnetic latitude. Lingenfelter and Ramaty

(1970) showed that, on average, the global production is $\sim 2.1 \text{ }^{14}\text{C cm}^{-2} \text{ s}^{-1}$.

Variations in the global ^{14}C production as a function of the geomagnetic field can be calculated using

$$\frac{Q(M = M(t))}{Q(M = M(0))} = \left[\frac{M(0)}{M(t)} \right]^{0.5}$$

where $M(t)$ and $M(0)$ are the past and present geomagnetic dipole moment, respectively. The present field is $M(0) = 8 \times 10^{25} \text{ gauss cm}^3$.

In addition, the following empirical relations are found for the production Q (in nuclei/ cm^2/s):

$$Q = 2.310 - 0.024aa$$

and

$$Q = 2.091 - 0.0041 < S >$$

where aa is the so-called geomagnetic aa index, and $<S>$ is the averaged sunspot number, as used by Stuiver and Quay (1980).

A high sunspot activity corresponds to a strong field, resulting in strong shielding, which scatters away more cosmic ray protons from Earth. Hence, less cosmic rays impinge on the Earth's atmosphere, resulting in less production of ^{14}C . In contrast, low sunspot activity corresponds to a weaker field, resulting in increased production of ^{14}C .

The Holocene

By radiocarbon dating of tree-rings of known calendar age, calibration curves are obtained. The most recent calibration curve is INTCAL09, published by Reimer et al. (2009). Using these curves, ^{14}C ages can be transformed into calendar ages, but this procedure is not mathematically straightforward because of the variations of the ^{14}C content in nature. Bronk Ramsey (1998) developed special software to calculate the probability distribution of calibrated ages that includes special procedures for 'wobble-matching' and 'sequencing'.

The dendrochronological part of INTCAL09 is shown in Figure 2. The data are not shown as calibration points on the graph but are plotted as $\Delta^{14}\text{C}$ (expressed in ‰). The $\Delta^{14}\text{C}$ signal is the deviation from the standard ^{14}C activity, corrected for radioactive decay, expressed in ‰. The $\Delta^{14}\text{C}$ signal is calculated as

$$\Delta^{14}\text{C} = \left[\exp \left(\frac{-\text{BP}}{8033} \right) \times \exp \left(\frac{\text{cal BP}}{8267} \right) - 1 \right] \times 1000 (‰)$$

Note that BP is the conventional ^{14}C age (i.e., activity measured relative to the standard), corrected for isotopic fractionation and calculated using the conventional half-life. The standard year corresponds to AD 1950. The historical date relative to AD 1950 is expressed in cal BP. The conventional half-life is $t_{1/2} = 5568$ years, yielding $t_{1/2}/\ln 2 = 8033$; the physical half-life is $t_{1/2} = 5730$ years yielding $t_{1/2}/\ln 2 = 8267$.

Currently, dendrochronology offers calibration back to 12 410 cal BP (Reimer et al., 2009). The absolute German Oak chronology presently extends to 10 429 cal BP, whereas the Preboreal Pine chronology covers the range of 9891–12 410 cal BP. The latter pine chronology was originally a floating chronology; it is now dendrochronologically matched to the absolute oak chronology, hence the pine chronology is absolute. The dendrochronological part of INTCAL09, thus, covers the complete Holocene and reaches back halfway into the Younger Dryas period.

Figure 1 Natural production of ^{14}C (number of nuclei/cm 2 /s) as a function of geomagnetic latitude.

Figure 2 Atmospheric ^{14}C content for the past 12 500 years, expressed in $\Delta^{14}\text{C}$ (‰). The $\Delta^{14}\text{C}$ is calculated from the INTCAL09 calibration dataset. Only the data derived from dendrochronology are shown. A long-term smoothing function is drawn through the data.

Smoothed curves can be drawn through the $\Delta^{14}\text{C}$ data, as is shown in Figure 2. This represents the long-term trend of the ^{14}C dataset. It had already been noted in the early days of radiocarbon that the data show a quasi-sinusoidal variation for the last 7000 years. Damon et al. (1989) showed that the data can be fitted with the following formula:

$$\Delta^{14}\text{C}(\text{‰}) = 35 + 51 \sin(5.826 \times 10^{-4} \text{ cal BP} - 2.401)$$

This function corresponds to a period of 10 780 years, an amplitude of 51‰ and a phase lag of 2.401 radians or 137.6°. The $\Delta^{14}\text{C}$ data fitted with this sine function are shown in Figure 3. Also shown are summarized data obtained by McElhinny and Senanayake (1982) of archaeomagnetic determinations of the Earth's magnetic dipole moment. These magnetic data show quasi-sinusoidal variation for the past ca. 10 000 years, with a maximum of about 40% above present-day value (ca. 6000 cal BP) and a minimum of 80% of present-day value (ca. 6000 cal BP). This shows that the long trend in the $\Delta^{14}\text{C}$ data is consistent with the variations in the geomagnetic values. The inverse relation between $\Delta^{14}\text{C}$ and the geomagnetic field is due to modulation of the ^{14}C production by the Earth's dipole moment.

Also, further back in time throughout the Holocene, the ^{14}C production rate variation induced by change in the geomagnetic dipole intensity appears to cause most of the long-term $\Delta^{14}\text{C}$ trend, as shown by Stuiver and Braziunas (1993).

Figure 4 shows the residual $\Delta^{14}\text{C}$ obtained by subtracting the long-term trend as shown in Figure 2. This means that for natural $\Delta^{14}\text{C}$ variations, the geomagnetic component is removed. The wiggles around this long-term trend, known as 'Suess wiggles,' are referred to as fine structures by Damon and Peristykh (2000). They represent forcing mechanisms other than the geomagnetic influence for cosmogenic isotope production that remain, such as solar, ocean, and possibly climatic forcing.

Figure 3 The atmospheric $\Delta^{14}\text{C}$ signal for the last 10 000 years, compared with archaeomagnetic determinations of the strength of the Earth's dipole moment. Data from McElhinny and Senanayake (1982).

Figure 4 Residual $\Delta^{14}\text{C}$ obtained by deducting the long-term trend as shown in [Figure 2](#).

Figure 5 A 50-year record of annual wine samples from the Republic of Georgia showing the 11-year sunspot cycle. Data from [Burchuladze et al. \(1980\)](#).

For the past millennium, this fine structure has been recognized in the known solar minima: the Dalton, Maunder, Spörer, Wolf, and Oort minima around AD 1825, 1700, 1500, 1350, and 1050, respectively. These solar minima correspond with an increase in $\Delta^{14}\text{C}$. Note that observation of sunspots has demonstrated the absence or dearth of sunspots during the Maunder Minimum, as discussed by [Eddy \(1976\)](#). This absence of sunspots is associated with lower solar wind intensity, and an increase in cosmic ray intensity and subsequent increased production of ^{14}C . Frequency analysis of the $\Delta^{14}\text{C}$ record shows dominant periods of approximately 2250, 208, and 89 years, as shown by [Damon and Peristykh \(2000\)](#) and [Damon et al. \(1989\)](#). Very prominent peaks, such as the 89-year cycle (the so-called Gleisberg cycle), are clearly solar in origin. There is evidence for lower frequency cycles (e.g., a 512-year period) that may have an origin in oceanic effects ([Damon and Peristykh, 2000](#)). In addition, the well-known 11-year solar cycle is present albeit with small amplitude. This is referred to as a ‘hyperfine’

structure and has been measured with high precision in annual wine samples from the Republic of Georgia ([Burchuladze et al., 1980](#)). These data are plotted in [Figure 5](#).

The ca. 2000-year oscillation in the $\Delta^{14}\text{C}$ record during the Holocene is synchronous with fluctuations in another cosmogenic isotope record, ^{10}Be , and climatic deterioration as observed in ice-rafted debris from deep sea cores. This observation in variability of the ^{14}C signal, therefore, plays an important role in climate-forcing research and solar effects, as discussed by [Bond et al. \(2001\)](#).

The tree-ring-based record of varying $\Delta^{14}\text{C}$ is used by [Solanki et al. \(2004\)](#) for reconstruction of the sunspot record during the Holocene. It shows that the current episode of high sunspot activity is the most intense for several thousand years. However, without a full understanding of the chain of cause and effect, we cannot be sure exactly how the changing Sun impacts our climate.

In this respect, it is interesting to note that rapid climatic oscillations, known as Dansgaard–Oeschger events, appear during the Late Glacial with a periodicity of ca. 1470 years. Modeling experiments by [Braun et al. \(2005\)](#) suggest that this climate cycle could have been triggered by solar forcing, despite the fact that a 1470-year solar cycle is absent.

The Deglaciation

For the Holocene, ^{14}C variations are well known and observed in the tree-ring record. The ^{14}C oscillations on decadal and century time scales can be explained as solar driven. For the Late Glacial and deglaciation periods, however, atmospheric ^{14}C has been influenced by ocean-related ^{14}C redistribution between the carbon reservoirs ([Stuiver et al., 1991](#)). The postulated mechanism for oceanic $\Delta^{14}\text{C}$ change is via the unstable thermohaline circulation in the North Atlantic, in which lowered salinity results in increased water stratification and reduced deep water formation. The latter, in turn, parallels reduced upwelling of ^{14}C -deficient water elsewhere in the oceans, thus increasing surface ocean and atmospheric $\Delta^{14}\text{C}$ levels ([Stuiver and Braziunas, 1993](#)). Simulations show that ventilation changes can cause fluctuations of 25‰ in atmospheric $\Delta^{14}\text{C}$. The rapid atmospheric $\Delta^{14}\text{C}$ rise at the onset of the Younger Dryas (50‰ in 200 calendar years), however, remains unexplained, as discussed by [Marchal et al. \(2001\)](#).

The tree-ring record is the most powerful tool for observing natural ^{14}C variations, because they are absolutely dated, and they represent an atmospheric ^{14}C signal. The dendrochronological record currently reaches 12 450 cal BP, well into the Younger Dryas interstadial ([Reimer et al., 2009](#)). This record is the backbone of the radiocarbon calibration curve. The latest calibration curve, INTCAL09 ([Reimer et al., 2009](#)), has been extended beyond the tree-ring record back to 50 000 cal BP. This extension is based on marine datasets: Foraminifera and corals dated by ^{14}C and corrected for a site-specific marine reservoir effect. The Foraminifera are from the Cariaco Basin of the coast of Venezuela, collected from laminated sediment which is matched to the absolute time scale ([Hughen et al., 2006](#)); the corals are from various Pacific Ocean sites and dated by U-series isotopes. They are selected to meet criteria established by the INTCAL working group ([Reimer et al., 2009](#)).

Figure 6 The atmospheric $\Delta^{14}\text{C}$ signal from INTCAL09 for the complete time range of the ^{14}C dating method (Reimer et al., 2009). This record is based on dendrochronology and (beyond ca. 12 400 years ago) on marine records.

Thus, the calibration curve for the time range beyond 12 450 cal BP is marine derived. The $\Delta^{14}\text{C}$ signal, corresponding to the complete INTCAL09 dataset, is shown in Figure 6 (and is an extension of Figure 2).

The Middle/Upper Paleolithic

The time range of the ^{14}C dating method is about 50 000 years; in exceptional cases, 60 000 years can be reached. Variations in the natural ^{14}C content are known from the calibration records that constitute INTCAL09 (Reimer et al., 2009). For the time range beyond the tree-ring record, that is, 12 410 cal BP, this period is currently developed from marine records. In general, a variety of data exist showing natural ^{14}C variations. They are derived from various natural archives, dated by both ^{14}C and another, independent method; for example, terrestrial macroremains (dated by ^{14}C) from laminated sediments (dated by varve counting) as measured by Kitagawa and van der Plicht (1998) and speleothems dated by both ^{14}C and U-series isotopes as measured by Hoffmann et al. (2010). All dating methods for such records have their advantages and disadvantages. The difficulties include such things as nonatmospheric ^{14}C materials (carbonates) that need reservoir corrections, varve counting errors, uncertainties in U-series isotope geochemistry, and uncertainties in ice core chronologies. For a more complete discussion of such records, see van der Plicht (2000). All these datasets show natural ^{14}C variations, some of them with large and thus far unexplained magnitudes.

Until recently, there was too much inconsistency between the datasets, such that calibration was not recommended because records could differ by as much as millennia (van der Plicht et al., 2004). As chronology is an essential ingredient for the Middle/Upper Paleolithic, this spawned debates in archaeology (Bronk Ramsey et al., 2006).

An overview of the most important data available for the complete ^{14}C dating range of 50 000–60 000 years is shown in Figure 7, which can be viewed as an extension of Figure 2 (showing the dendrochronological record). For clarity, the dendrochronological record is not shown again here. The data are as follows: terrestrial macrofossils from laminated

Figure 7 The $\Delta^{14}\text{C}$ data from selected individual 'calibration' records beyond dendrochronology. Note that errors along the horizontal axis are not shown.

sediment from Lake Suigetsu, Japan (Kitagawa and van der Plicht, 1998); a speleothem record from the Bahamas (Hoffmann et al., 2010); Foraminifera from the Cariaco Basin (Hughen et al., 2006); Foraminifera from the Iberian Sea (Bard et al., 2004); Atlantic and Pacific corals (Fairbanks et al. (2005); and furthermore, a speleothem record from Socotra, Arabia; North Atlantic Foraminifera; and calcite from Lake Lisan (Israel) deposits. For full references, see van der Plicht et al. (2004) or Reimer et al. (2009).

The data shown here are plotted as $\Delta^{14}\text{C}$. Note that for calculating $\Delta^{14}\text{C}$, the absolute age must be included, so the plot may be misleading. In addition, the errors along the horizontal axis (the 'absolute timescale') are not shown because they are not known.

Older data with large errors (based on alpha spectrometric U-series measurements, TL/OSL/ESR dates, etc.) are not shown here – see van der Plicht (2000) for these data and references listed.

The extremes are represented by the Japanese varve record (Kitagawa and van der Plicht, 1998) and the Bahamian speleothem (Hoffmann et al., 2010). In the Japanese varve record, the natural ^{14}C content – which is elevated back to 26 000 cal BP – tends to go back to present levels around 30 000 cal BP. Note that this record is the only one based on terrestrial/atmospheric sample material. Its weakness is the possible presence of hiatuses, which cannot be excluded. The other extreme is represented by the speleothem records, for which carbonate material is dated by both ^{14}C and U-series isotopes.

Excursions are shown in the Cariaco Basin record by Hughen et al. (2004), at ca. 35 000 and 41 000 cal BP. These correspond to geomagnetic excursions known as Mono Lake and Laschamps, respectively.

The Cariaco curve is almost an 'average' of the Bahamian speleothem and the Japanese varve datasets (see Figure 7). Note that the absolute timescale for the Cariaco Basin record is the GISP2 ice core timescale of Meese et al. (1997).

The production of cosmogenic isotopes – ^{14}C and also ^{10}Be , ^{26}Al , ^{36}Cl , ^{41}Ca – and variations therein on the century/millennium timescale are determined mainly by the geomagnetic field strength.

Mono Lake and Laschamp-type excursions are observed in cosmogenic isotopes, other than ^{14}C , in various records: for ^{10}Be in Antarctic ice cores, Greenland ice cores and in marine sediments; and for ^{36}Cl in Greenland ice cores and terrestrial packrat mittens. References can be found in the review by van der Plicht (2000).

Paleomagnetic fields can be obtained from remanence measurements, such as data from Tric et al. (1992), as shown in Figure 8. Other measurements show a general similar pattern: high values around 50 ka ago, followed by a distinct minimum around 40 ka.

When comparing Figures 7 and 8, it appears that, in general, the ^{14}C levels in the atmosphere compared with the geomagnetic dipole moment over the past 50 ka reveal a clear inverse relationship. Quantitatively, the ^{14}C variations appear to be of the right order of magnitude.

Differences between various paleomagnetic records can be ascribed to the effect of localized nondipole fields and to variations in the magnetic properties of the minerals in the sediment. It is difficult to derive the global dipole moment from the data.

The cosmogenic isotope ^{14}C is part of the global C cycle and depends on the dynamics of the carbon system on Earth. Most of the exchangeable carbon is dissolved and held in the deep oceans, which have a relatively slow turnover time. The result is that the ^{14}C levels in the atmosphere and terrestrial biosphere lag behind any change in the production rate caused by an alteration in the geomagnetic dipole field intensity. A further

complication is a changing ventilation rate of the oceans during glaciation.

Paleomagnetic fields can also be reconstructed using cosmogenic isotope deposition records. Geomagnetic field intensity variations, however, are not the only factor that has influenced the cosmogenic nuclide records. In the case of ^{14}C , variations of the global carbon cycle (caused by reorganizations of the ocean circulation patterns from the Last Glacial to the present interglacial) and solar variations are superimposed.

The ^{10}Be nuclides are not affected by these variations because they are part of a very different geochemical cycle. The signal depends on precipitation and climate; in addition, its deposition rates in marine sediments vary as a function of lateral sediment redistribution.

Mazaud et al. (1991) constructed the ^{14}C production rate based on the data from Tric et al. (1992) as shown in Figure 8. Muscheler et al. (2005) calculated cosmogenic isotope production based on ^{10}Be deposition rates.

Paleomagnetic field reconstruction based on cosmogenic isotopes has the advantage that it is complementary to methods based on remanence measurements. This production is sensitive mainly to the dipole moment as the shielding effect of the nondipole components decreases faster with increasing distance from Earth. The modulation of cosmic rays takes place in space, far outside the atmosphere, where the effect of nondipole fields is negligible.

In contrast, remanence measurements in volcanic rocks or sediments are based on spot measurements on the Earth's surface that might be influenced by changes in quadrupole (or higher) moments of the field.

The Anthropogenic Era

During the past century, the atmospheric ^{14}C signal has largely been influenced by two different anthropogenic effects: fossil fuel burning and nuclear explosions. Fossil fuels have geological age; hence, all of their ^{14}C has decayed. The combustion of fossil fuels adds ^{14}C -free CO_2 into the atmosphere; this dilution causes the atmospheric ^{14}C content to decrease. This effect (known as the 'Suess effect') is clearly seen in (pre)modern tree-rings (Figure 9(a)). Since the onset of the industrial revolution, the atmospheric ^{14}C content had decreased by 2% in 1950. Since ca. 1950, the Suess effect is no longer directly visible because a large amount of artificial ^{14}C has been injected into the atmosphere by nuclear explosions. As a result, the ^{14}C concentration in the atmosphere increased in 1963 by a factor of 2 in the Northern Hemisphere and with a somewhat smaller factor in the Southern Hemisphere. Since the Nuclear Test Ban Treaty came into effect in 1963, the ^{14}C concentration in the atmosphere has been decreasing due to rapid exchange between atmosphere and other carbon reservoirs, mainly the ocean and the biosphere. A selection of data is shown in Figure 9(b) (see Meijer et al., 1994 and references therein).

The large pulse of artificial ^{14}C injected into the atmosphere (the so-called 'bomb peak') enables the use of ^{14}C as a tracer for studying the global carbon cycle (Levin and Hessheimer, 2000; Levin et al., 2008). The bomb peak is a spike that can be

Figure 8 Geomagnetic dipole field (virtual dipole moment, VDM) changes for the past 80 000 years based on paleomagnetic measurements. Reproduced from Tric E, Valet JP, Turcholka P, et al. (1992) Paleointensity of the geomagnetic field during the last 80 000 years. *Journal of Geophysical Research* 97(B6): 9337–9351.

Figure 9 Modern anthropogenic influence on the atmospheric ^{14}C content: (a) the Suess effect – burning of fossil fuels caused the atmospheric $\Delta^{14}\text{C}$ signal to decrease until ca. 1950 (data from Stuiver and Quay, 1980); (b) the bomb effect – until 1963, the atmospheric $\Delta^{14}\text{C}$ signal increased sharply due to atmospheric nuclear explosions.

used for dating modern soils and peat deposits. In addition, the bomb peak can be used for dating in forensic and biomedical applications.

Conclusion

The cosmogenic isotope ^{14}C has many applications in the dating of late quaternary events, particularly the dating of organic remains back to 50 000 years ago. The ^{14}C timescale needs to be calibrated into calendar ages because of variations in the atmospheric ^{14}C content through time. These variations yield scientific information on matters such as forcing of climate change, carbon cycle research, cosmogenic isotope production, and solar fluctuations.

The ^{14}C calibration record, which yields the $\Delta^{14}\text{C}$ signal, is well known for the Holocene based on tree-ring records, which extend back to more than 12 000 years ago. The curve is extended back to 50 000 years ago based on marine records. There has been remarkable progress in obtaining calibration datasets and, thus, a record for past $\Delta^{14}\text{C}$. But the oldest part of the record is still to be considered as ‘work in progress,’ as not all terrestrial records are consistent and there are uncertainties in ^{14}C reservoir corrections for the marine records. What is still needed is a set of well-established anchor points for both timescales – ^{14}C and absolute. A truly terrestrial calibration curve may not be too far away, if chronologies based on Kauri trees can be established (Balter, 2006). This would provide a record of natural $\Delta^{14}\text{C}$ variations without ambiguities, giving a better insight into changes in the Earth’s system in the past 50 000 years.

Causes of Temporal ^{14}C Variations

Introduction

A principal assumption underlying the radiocarbon dating method is that the amount of radiocarbon (^{14}C) in the atmosphere is constant over the useful range of the technique (Libby, 1955). In the calculation of a radiocarbon age, the ^{14}C content of a sample is measured relative to a standard, and that standard is chosen to reflect a fixed atmospheric ^{14}C value. It is now known that the ^{14}C content of the atmosphere is not invariant; however, radiocarbon age calculations continue to assume constant atmospheric ^{14}C . This is done with the caveat that ages are quoted in radiocarbon years and are distinguished from calendar years. To account for the difference, radiocarbon years are calibrated to calendar years using detailed information about the radiocarbon content of the atmosphere at the time the sample formed.

The key to understanding atmospheric radiocarbon variations through time is the development of time series records that reflect prehistoric atmospheric ^{14}C values. The most precise time series of this type is based on tree rings. Trees absorb carbon dioxide and sample the atmosphere as they grow. Certain trees form distinct annual rings and can be dated very accurately using dendrochronology. Dendrochronological dates are used to fix the calendar age of a tree ring, and ^{14}C measurements on the wood determine the atmospheric radiocarbon at the time the tree grew. The first measurements of this type began in the 1950s when it was observed that the radiocarbon content of the atmosphere was not static (de Vries, 1958; Suess, 1954). Today, an internationally agreed-upon composite tree-ring record (INTCAL09, Reimer et al., 2009) is available to convert radiocarbon dates to calendar dates. Implicit in this conversion is a correction for temporal variability in atmospheric radiocarbon. The current tree-ring record contains thousands of radiocarbon measurements and provides a continuous record with annual to decadal resolution for about the last 12 600 years. The curve is a compilation of results for trees from North America and Europe.

Beyond the limit of the tree-ring calibration, it is necessary to rely on other geological archives to document past atmospheric ^{14}C variations. These include (1) lake and ocean sediments, calibrated by counting varved layers, or with $\delta^{18}\text{O}$ profiles from the same cores; and (2) corals, sediments, or speleothems dated directly with U–Th isotopes. None of these techniques provide time series records with the precision or resolution of the tree-ring record; however, they do allow meaningful inferences to be made about temporal atmospheric ^{14}C variations beyond 12 600 years, to the limit of the radiocarbon method at about 50 000 years.

Natural Radiocarbon Variations

The impetus for developing radiocarbon time series was driven by the need to achieve accurate radiocarbon dates with respect

to calendar ages. These time series also provide fundamental insights into processes that affect the amount and distribution of carbon on Earth. There are three fundamental natural processes that affect atmospheric radiocarbon, including (1) changes in the Earth's geomagnetic field, (2) variable solar activity, and (3) carbon cycle dynamics. Changes in the Earth's geomagnetic field over the past 50 000 years are now well known and the effect of these changes on atmospheric radiocarbon is also understood. This variability occurs over thousands of years. Solar activity produces periodic variations on time scales of years to hundreds of years. Carbon cycle dynamics affect the net amount of carbon in the atmosphere at any given time, and the rate of carbon exchange between different reservoirs on the Earth's surface. The balance established by the carbon cycle reflects the contemporary global climate.

Anthropogenic Radiocarbon Variations

Radiocarbon is a useful tracer because it is carried in carbon dioxide molecules, a key component in Earth's carbon cycle. In addition to the natural influences governing atmospheric ^{14}C , there are three measurable anthropogenic influences. The first is a small (about 2%) decrease in the amount of atmospheric radiocarbon over the past several centuries. This effect was caused by the widespread use of fossil fuels, which are depleted in ^{14}C , sometimes referred to as the industrial effect. The industrial effect began to have a significant impact on atmospheric ^{14}C in the late seventeenth century and continues to influence atmospheric radiocarbon today. A second anthropogenic influence on atmospheric ^{14}C was the production of radiocarbon by nuclear weapons testing. This effect began to increase atmospheric radiocarbon in the mid-1950s. There is a distinct maximum in atmospheric radiocarbon that occurred in 1963, when the Partial Test Ban Treaty, prohibiting atmospheric detonation of nuclear weapons, was signed. A third, and relatively minor source of atmospheric radiocarbon, is produced as a by-product of the nuclear energy industry.

Definitions

The definition of a radiocarbon date includes several conventions that need to be stated explicitly to preface the discussion of temporal radiocarbon variations. These conventions were developed by the radiocarbon community over many years and formalized by Stuiver and Polach (1977). They are as follows:

1. The present year for radiocarbon dating is defined as AD 1950. This date corresponds to the time when the radiocarbon technique was first developed. Radiocarbon dates are expressed in years before present (BP) or years before 1950.
2. The half-life for a radiocarbon measurement is assumed to be 5568 years (the 'Libby' half-life).

- As stated earlier, the original amount of radiocarbon in the atmosphere is assumed to be a constant and known value. This value is quantified using the National Institute of Standards and Technology (NIST – formerly, National Bureau of Standards) Oxalic Acid I standard (NIST-SRM-4990B). Secondary standards used for analysis are adjusted to the original NIST Oxalic Acid I standard value.
- Radiocarbon measurements are normalized for isotopic fractionation by adjusting the measured activities, or carbon isotope ratios, to $\delta^{13}\text{C} = -25\text{‰}$ (see below).

Two of the statements (nos. 2 and 3) listed above are not valid. The actual half-life of radiocarbon is closer to 5730 years, and the amount of radiocarbon in the atmosphere is not invariant. However, the operational definition outlined earlier ensures consistent reporting between different laboratories and makes comparisons of radiocarbon dates unambiguous. The inaccuracies implicit in this definition are removed when the radiocarbon ages are converted to calendar years using a calibration curve.

Correction for Isotopic Fractionation – $\delta^{13}\text{C}$ Correction

The adjustment of a radiocarbon measurement to remove isotopic fractionation is a critical point when discussing temporal ^{14}C variations because some temporal ^{14}C variations have amplitudes that are of the same magnitude as the corrections. Carbon has two stable isotopes – ^{12}C and ^{13}C . The ratio of these two isotopes is essentially the same everywhere in the atmosphere; however, this ratio may be changed when carbon is removed from the atmosphere, for example, through photosynthesis. When plants absorb carbon dioxide from the atmosphere, they discriminate against both ^{13}C and ^{14}C , relative to ^{12}C . This gives plants slightly reduced $^{13}\text{C}/^{12}\text{C}$ ratios, as compared with the contemporary atmosphere in which they grew. For the purposes of radiocarbon measurement, it is necessary to adjust for these small differences by normalizing the measured radiocarbon content to correspond to a uniform $^{13}\text{C}/^{12}\text{C}$ value. To facilitate comparison of $^{13}\text{C}/^{12}\text{C}$ ratios, they are expressed in the δ notation as follows:

$$\delta^{13}\text{C} = \left[\frac{\left(\frac{^{13}\text{C}}{^{12}\text{C}} \right)_s}{\left(\frac{^{13}\text{C}}{^{12}\text{C}} \right)_{\text{STD}}} - 1 \right] \times 1000\text{‰}$$

where $(^{13}\text{C}/^{12}\text{C})_s$ is the ratio of a sample and $(^{13}\text{C}/^{12}\text{C})_{\text{STD}}$ is the ratio in the standard. $\delta^{13}\text{C}$ is a unitless proportion, like percent, and is quoted in parts per thousand, or permil (‰). The standard for $\delta^{13}\text{C}$ is a marine carbonate, so samples from the ocean have $\delta^{13}\text{C}$ values close to zero. Radiocarbon dates are adjusted to $\delta^{13}\text{C} = -25\text{‰}$, which is a typical value for trees.

Calculation of $\Delta^{14}\text{C}$

The quantity $\Delta^{14}\text{C}$ is useful when describing temporal radiocarbon variations (relative radiocarbon isotope ratio, units of permil (‰)). Radiocarbon dates expressed in years before present (BP), present $\equiv$ AD 1950. Half-life of $^{14}\text{C} \equiv 5568$ years (the 'Libby' half-life)). $\Delta^{14}\text{C}$ values express the difference between the sample and the modern atmosphere (AD 1950). There are

two ways to calculate $\Delta^{14}\text{C}$, depending on how one measures the amount of radiocarbon, comprising (1) decay counting or (2) mass spectrometry (measuring isotopic ratios). Counting laboratories measure decay rates (activities) based on the number of beta particles counted per unit time, from the decay of ^{14}C . In a counting laboratory, the activity of ^{14}C is measured in disintegrations per minute (dpm). This is the sample activity A_s . To normalize the sample to $\delta^{13}\text{C} = -25\text{‰}$, A_s may be recalculated to the normalized sample activity A_{SN} using the equation (Donahue et al., 1990):

$$A_{\text{SN}} = A_s \left[\frac{1 - \frac{25}{1000}}{\delta^{13}\text{C} + \frac{1}{1000}} \right]^2$$

In this expression, $\delta^{13}\text{C}$ is measured from the sample. The exponent in the expression is related to the mass difference between ^{14}C and ^{12}C (two atomic mass units). $\Delta^{14}\text{C}$ is then calculated as (Stuiver and Polach, 1977):

$$\Delta^{14}\text{C} = \left[\frac{A_{\text{SN}} e^{\lambda(1950-t)}}{A_{\text{ON}}} - 1 \right] \times 1000\text{‰}$$

where t is the age of the sample in calendar years, λ is the decay constant for ^{14}C appropriate for the 5730 year half-life, and A_{ON} is the activity of the oxalic acid standard at 1950, normalized to -19‰ . Notice that when $\Delta^{14}\text{C}$ is positive, then the sample has a greater ^{14}C activity than the 1950 atmospheric level, and when $\Delta^{14}\text{C}$ is negative, the sample has a smaller ^{14}C activity than the 1950 atmospheric level. In this expression, the age of the sample, t , must be known from independent information.

Accelerator mass spectrometry (AMS) laboratories measure sample isotope ratios instead of sample activities. Either $^{14}\text{C}/^{13}\text{C}$ ratios or $^{14}\text{C}/^{12}\text{C}$ ratios may be utilized for radiocarbon dating purposes. In the case of $^{14}\text{C}/^{13}\text{C}$, the normalized sample ratio, $(^{14}\text{C}/^{13}\text{C})_{\text{SN}}$, is calculated using the formula (Donahue et al., 1990):

$$\left(\frac{^{14}\text{C}}{^{13}\text{C}} \right)_{\text{SN}} = \left(\frac{^{14}\text{C}}{^{13}\text{C}} \right)_s \left[\frac{1 - \frac{25}{1000}}{\delta^{13}\text{C} + \frac{1}{1000}} \right]$$

where $(^{14}\text{C}/^{13}\text{C})_s$ is the measured ratio for the sample and the $\delta^{13}\text{C}$ value is measured from the sample. Notice that when measuring $^{14}\text{C}/^{13}\text{C}$ ratios, the exponent in the conversion factor is reduced to 1 because the difference in mass between the two isotopes is 1 atomic mass unit.

The fraction modern carbon (F) value is calculated as

$$F = \frac{(^{14}\text{C}/^{13}\text{C})_{\text{SN}}}{(^{14}\text{C}/^{13}\text{C})_{\text{ON}}}$$

where $(^{14}\text{C}/^{13}\text{C})_{\text{ON}}$ is the measured ratio for the oxalic acid standard, normalized to its value in 1950, with $\delta^{13}\text{C} = -19\text{‰}$.

For AMS measurements, $\Delta^{14}\text{C}$ may be calculated as follows:

$$\Delta^{14}\text{C} = F e^{\lambda(1950-t)}$$

Counting and mass spectrometry yield equivalent results and the time series discussed in the following sections come from both sources.

Natural Radiocarbon Variations

Radiocarbon is one of many cosmogenic isotopes produced continuously in the upper atmosphere (Lal and Peters, 1967). It is formed predominantly by the reaction $^{14}\text{N}(\text{n},\text{p})^{14}\text{C}$ (Libby, 1955). The global average production of ^{14}C is currently about $2 \text{ atoms cm}^{-2}\text{s}^{-1}$ and the vast bulk of this production is in the atmosphere. Radiocarbon is also produced *in situ* in the lithosphere and hydrosphere, but in negligible amounts. The production of ^{14}C depends on galactic cosmic rays (GCRs), composed primarily of high-energy protons. Although the GCR flux has been constant on a timescale of millions of years (Lal, 1974), it is modulated by the Earth's magnetic field (geomagnetic field) and the Sun's magnetic field (heliomagnetic field), producing temporal variations (Castignoli and Lal, 1980). This temporal variability affects the number of secondary thermal neutrons produced by nuclear reactions between cosmic rays and atmospheric molecules. Once radiocarbon is produced in the atmosphere, it is subject to further temporal fluctuations associated with the transport and exchange of carbon between different carbon reservoirs, through the carbon cycle. These factors are discussed in the next section.

^{14}C Variability Related to Earth's Geomagnetic Field

The Earth's geomagnetic field directly influences the production of radiocarbon in the atmosphere. It serves to deflect incoming galactic cosmic radiation. The geomagnetic field is not homogeneous and the production of ^{14}C is highest at the poles where magnetic field lines are steeply inclined (Figure 1). The geomagnetic influence on radiocarbon production operates on a scale of thousands of years. Figure 2(a) shows the marked decrease in $\Delta^{14}\text{C}$, which has occurred over the past 50 000 years. Figure 2(b) shows a relative paleointensity curve for the Earth's geomagnetic field inferred from globally distributed marine sediment records (Guyodo and Valet, 1999). It can be seen by comparison of the two figures that the radiocarbon content of the atmosphere is inversely related to the geomagnetic field strength. This finding was first shown

Figure 1 Diagrammatic sketch of the geomagnetic field surrounding the Earth. The geomagnetic field deflects cosmic radiation most strongly at the Equator, where the geomagnetic field is subparallel to the planet's surface.

by Suess (1970) and Bucha (1970). Bard et al. (1990) were the first to document atmospheric $\Delta^{14}\text{C}$ variations beyond the limit of the tree-ring record, where radiocarbon dates diverge from calendar ages by thousands of years. Although a first-order correlation between the geomagnetic field strength and atmospheric ^{14}C is evident, this does not account for all the long-term variability. The details are complicated by multiple ^{14}C pathways in nature within the carbon cycle.

It is worth noting that time series of ^{10}Be , another cosmogenic isotope produced in the atmosphere, are more closely tied to the Earth's geomagnetic field intensity than radiocarbon (McHargue et al., 1995). This is because ^{10}Be has an atmospheric residence time of less than one year. A well-known feature of ^{10}Be studies is a striking maximum in ^{10}Be production between about 35 and 45 ka BP that was observed first in polar ice cores (Raisbeck et al., 1987) and later in marine and lake sediments. Radiocarbon scientists have made an effort to identify a radiocarbon excess from this time period; however, this is more difficult for ^{14}C than for ^{10}Be . As the 35–45 ka BP period is about six radiocarbon half-lives BP, the original ^{14}C signal would have decayed to about 1% or 2% of its original magnitude. This is not true for ^{10}Be , which has a half-life of 1.3 million years.

^{14}C Variability Related to Solar Activity

Atmospheric radiocarbon production is influenced by the Sun's heliomagnetic field in the same sense that it is affected by the Earth's geomagnetic field. On a timescale of years, the heliomagnetic field modulates the GCR flux in a periodic manner. A well-known example of this behavior is observed in the 22-year solar cycle from sunspot time series. A sunspot is a relatively cool region of the Sun's surface characterized by intense magnetic activity. Sunspots were first observed by Galileo and sunspot records extend back in time for centuries. Every 11 years, the heliosphere reverses polarity producing an 11-year periodicity and a 22-year cycle.

As solar variations exhibit periodicities, it is possible to use spectral analyses of $\Delta^{14}\text{C}$ time series to search for changes in past solar activity, predating those known from historical sunspot records. Stuiver and Braziunas (1993) used the Maximum Entropy Method of spectral analysis to study a tree-ring time series with annual resolution, covering the past 450 years. This effort yielded a 10.4-year periodicity, which the authors attributed to the Sun's 11-year cycle. They used the same method to identify a 206-year solar period from a bidecadal time series. In a similar study, Damon and Peristykh (2000) used a discrete Fourier transform method to identify the same 10.4-year period from an annual tree-ring record. The authors also identified a prominent 88-year solar period and a 207-year solar period from a decadal tree-ring record (Figure 3). Such studies require the highest possible precisions for $\Delta^{14}\text{C}$ ($\pm 2\%$), currently obtained only from tree rings.

The Sun also varies on longer time scales and the amplitude of sunspot number variation changes with time as well. Relatively few sunspots occurred between about 1645 and 1715, a period known as the Maunder minimum. This period is plainly evident in decadal tree-ring radiocarbon time series (Figure 4), and was first recognized by Stuiver (1961). Elevated

Figure 2 (a) Inferred atmospheric $\Delta^{14}\text{C}$ for the last 50 ka. Data from the INTCAL09 data compilation (Reimer et al., 2009). (b) Relative paleomagnetic field intensity of the Earth for the last 50 ka. Data from the SINT800 record (Guyodo and Valet, 1999). Note the inverse relationship between the relative magnetic intensity and atmospheric $\Delta^{14}\text{C}$.

Figure 3 Fourier spectrum of detrended decadal $\Delta^{14}\text{C}$ data. Reproduced from Damon PE and Peristykh AN (2000) Radiocarbon calibration and application to Geophysics, Solar Physics and Astrophysics. *Radiocarbon* 42: 137–150.

$\Delta^{14}\text{C}$ values during this period resulted from reduced heliomagnetic field intensities, which permitted a larger number of GCRs to enter the Earth's atmosphere. There have also been times when the heliomagnetic field was stronger than it is today, and there is evidence of protracted periods of reduced or enhanced heliomagnetic field intensities that lasted thousands of years (Lal et al., 2005). These were detected in ice core samples from Summit, Greenland. Polar ice contains *in situ* ^{14}C whose production is not influenced by the Earth's geomagnetic field or by changes in the carbon cycle. Hence, ice core samples are able to provide a direct record of heliomagnetic field intensity. Lal et al. (2005) found two periods of enhanced radiocarbon production, by a factor of ~ 2 (8.5–9.5 and 27–32 ka BP);

and a period of reduced radiocarbon production, by a factor of ~ 1.5 (12–16 ka BP).

^{14}C production by solar flares

A solar flare is a sudden outburst of particles from the Sun's surface. Radiation from these bursts is emitted across a wide range of the electromagnetic spectrum. Some particles travel to the Earth's atmosphere and produce secondary thermal neutrons in the same manner as GCRs. Lingenfelter and Ramaty (1970) demonstrated that a single solar flare can produce measurable increases in atmospheric $\Delta^{14}\text{C}$. For example, they calculated that a particular solar flare, which occurred on 23 February 1956, is expected to have caused a 7.5‰ increase

Figure 4 Atmospheric $\Delta^{14}\text{C}$ for the last 16 ka from the INTCAL98 tree-ring compilation. Inset shows solar minima (Oort, Wolf, Spörer, Maunder, and Dalton) which appear as $\Delta^{14}\text{C}$ maxima in the unfiltered data. Reproduced from Damon PE and Peristykh AN (2000) Radiocarbon calibration and application to Geophysics, Solar Physics and Astrophysics. *Radiocarbon* 42: 137–150.

in the contemporary level of atmospheric $\Delta^{14}\text{C}$. This was one of the strongest flares on record (10^{31} – 10^{32} ergs), but not a particularly rare one. Similar flares occurred on 29 September 1989; 28 October 2003; and 2–4 November 2003. Lingenfelter and Ramaty noted that the solar flare contribution to the global atmospheric ^{14}C in 1956 was impossible to resolve due to a much larger concurrent increase in atmospheric ^{14}C from above ground nuclear tests. Scientists have looked to tree-ring time series to identify solar flare components, but the radiocarbon produced by flares is diluted by the relatively large inventory of ^{14}C already in the atmosphere. In addition, the annual resolution of tree rings is too long to identify solar flares that may last hours or days. The effect of solar flares on atmospheric radiocarbon production is counterintuitive. Solar flares enhance ^{14}C production, while sunspot maxima imply reduced ^{14}C production. Both effects tend to occur at the same time. It is clear from Figure 4 that the latter effect has been more significant over the past millennium.

^{14}C production by supernovae

Lingenfelter and Ramaty (1970) also considered the possibility of producing atmospheric ^{14}C from nearby supernovas. They identified two potential pathways of atmospheric radiocarbon production related to supernovas: (1) a short-term increase produced by gamma rays made in the explosion and (2) a much longer-term transient increase produced by direct enhancement of the GCR flux. Damon and others investigated the possibility of elevated atmospheric ^{14}C from a supernova that was observed in AD 1006. Of all supernovas on record, this supernova was the brightest and closest to Earth. Figure 5 shows an annually resolved tree-ring time series from AD 1003 to AD 1030, which features a sharply rising 2-year $\Delta^{14}\text{C}$ pulse with an amplitude of 8‰, possibly related to the 1006 supernova.

^{14}C Variability Related to the Carbon Cycle

Once ^{14}C forms in the upper atmosphere, it rapidly oxidizes to carbon dioxide and becomes efficiently mixed by atmospheric transport and gas exchange. This results in a nearly homogeneous atmospheric ^{14}C content at any given time. The fate of a particular carbon dioxide molecule is subsequently controlled by the carbon cycle, and by extension, the amount of ^{14}C in the atmosphere at any given time is also controlled by carbon cycle dynamics. The carbon cycle connects carbon reservoirs of the atmosphere, hydrosphere, biosphere, and lithosphere in a dynamic balance (Figure 6). More than 90% of the Earth's exchangeable carbon is in the ocean and less than 2% is in the atmosphere. Hence, ocean–atmosphere coupling is strongly leveraged by the mass of carbon in the ocean. Ocean–atmosphere exchange, in particular, exerts dominant temporal control over the amount of CO_2 and ^{14}C in the atmosphere.

The carbon cycle balance can be understood in terms of (1) the number and size of carbon reservoirs on Earth, (2) the exchange mechanisms that transfer carbon between these reservoirs, (3) the rates of exchange between carbon reservoirs, and (4) the dynamics that control the balance of the various exchange pathways. Of particular interest is how these factors might have changed during the past 50 000 years. Studies from the 1950s began to trace the movement of CO_2 between the oceans and the atmosphere, and within the ocean depths using mass balance, or box models to describe the carbon cycle (Craig, 1957; Revelle and Suess, 1957). A key finding in subsequent work was that the ocean is naturally divided into two reservoirs: (1) a thin surface layer (above the thermocline) that exchanges very quickly with the atmosphere (on order 10–20 years), and (2) a much larger deep ocean reservoir that exchanges very slowly (on order thousands of years). This structure was incorporated into the model of

Figure 5 A small but distinct atmospheric $\Delta^{14}\text{C}$ peak that could be related to a supernova observed on 30 April 1006. Reproduced from Damon PE and Peristykh AN (2000) Radiocarbon calibration and application to Geophysics, Solar Physics and Astrophysics. *Radiocarbon* 42: 137–150.

Figure 6 Diagrammatic representation of the carbon cycle. Radiocarbon is produced from secondary thermal neutrons in the atmosphere. The deep ocean is the largest carbon reservoir on Earth. The surface ocean rapidly exchanges with the atmosphere, over a decade or two.

Oeschger et al. (1975) who distinguished a mixed-surface ocean carbon reservoir from a deep ocean carbon reservoir. Their model reliably predicted the major features of atmospheric ^{14}C variability in the latter half of the twentieth century, following massive inputs of bomb-produced ^{14}C .

Mass balance models are more loosely constrained during times of climate change, such as during the last Ice Age. This is because the amount and rate of carbon exchange between reservoirs varied substantially in the past, and the details of these changes are unknown. The Last Glacial Maximum occurred approximately 20 000 years ago, and since then, sea

level has risen over 120 m. This implies large carbon reservoir changes, unseen during the Holocene, where the atmospheric radiocarbon record is well established. The most recent large change in atmospheric radiocarbon occurred 11 000–12 000 calendar years ago. This 10% drop in $\Delta^{14}\text{C}$ was first observed in corals from Papua New Guinea (Edwards et al., 1993). This feature is very likely related to climate change associated with the Younger Dryas climatic event.

Anthropogenic Radiocarbon Variations

Man's activities have left a distinct imprint on the atmospheric radiocarbon record. Three primary anthropogenic inputs can be identified in the atmosphere: (1) ^{14}C -depleted carbon from fossil fuel burning, (2) radiocarbon from nuclear weapons testing, and (3) radiocarbon from nuclear fuels reprocessing.

Fossil Fuels

Anthropogenic effects were first recognized by Suess (1954), who observed a 2% reduction in atmospheric ^{14}C starting in the early eighteenth Century (Figure 7). This reduction was caused by the onset of the industrial revolution. The atmospheric inventory of ^{14}C became diluted when humans began to burn fossil fuels in large amounts. Fossil fuels are typically millions of years old and any radiocarbon in the fuels has long since decayed away. Fossil fuel burning produced a gradual drop in $\Delta^{14}\text{C}$ over time. A side effect of the drop in radiocarbon is a ^{14}C age plateau, which makes it impossible to distinguish radiocarbon ages between the eighteenth and twentieth centuries.

Figure 7 Industrial effect on atmospheric $\Delta^{14}\text{C}$ over the past several centuries. A broad plateau exists because of fossil fuel burning. First identified by Suess (1954). Data is from the INTCAL09 dataset (Reimer et al., 2009).

Figure 8 Atmospheric radiocarbon from nuclear weapons testing in the 1950s and 1960s. Note the different amplitude and rate of increase in the Southern Hemisphere, as compared with the Northern Hemisphere. Zones represented in the figure are NH1 – Northern Hemisphere high latitude sites, NH2 and NH3 – Northern Hemisphere mid- to low latitude sites, SH – Southern Hemisphere. Reproduced from Hua Q and Barbetti M (2004) Review of tropospheric bomb ^{14}C data for carbon cycle modeling and age calibration purposes. *Radiocarbon* 46: 1273–1298.

Nuclear Weapons Testing and Nuclear Power

When Libby first published on the radiocarbon method, anthropogenic inputs of radiocarbon were minimal. Within 10 years however, worldwide nuclear weapons testing would nearly double the amount of radiocarbon in the Earth's atmosphere. Anthropogenic radiocarbon was injected into the stratosphere during these tests and it entered the troposphere within a couple of years (Nydal, 1963). Atmospheric ^{14}C increased rapidly in the Northern Hemisphere, with the highest $\Delta^{14}\text{C}$ levels occurring in the mid- to high latitudes (Figure 8). Very few tests were made in the Southern Hemisphere and atmospheric $\Delta^{14}\text{C}$ changed more slowly there, with reduced peak radiocarbon levels. The maximum amplitude of the ^{14}C perturbation in the Northern Hemisphere was reached in 1963, around the time when the Partial Test Ban Treaty was signed. After 1963, the radiocarbon content of the atmosphere dropped off sharply. Within 10 years, atmospheric ^{14}C was reduced to about one half of its peak levels. This reduction was primarily due to the efficient exchange of CO_2 between the atmosphere and the surface ocean. While the atmosphere continued to drop, surface ocean values rose, with peak values occurring around 1970 (Linick, 1980; Nydal et al., 1980). Figure 9

illustrates the dramatic increases which occurred in the surface ocean during the 1960s. Surface ocean ^{14}C is seen to steadily increase from the late 1950s to 1972, when it reached peak $\Delta^{14}\text{C}$ values of approximately 200‰. Figure 9 also illustrates the utility of ^{14}C as a chemical tracer, showing evidence of equatorial upwelling associated with low $\Delta^{14}\text{C}$ values, and enhanced CO_2 exchange in oceanic gyres at mid-latitudes showing relatively high $\Delta^{14}\text{C}$ values. This aspect of the anthropogenic input of ^{14}C made it ideal for tracer studies of the carbon cycle (Damon et al., 1978).

To the benefit of all, radiocarbon is no longer being produced in large amounts by nuclear weapons testing. However, it is still being released into the atmosphere as a by-product of the nuclear power industry. At the LaHague reprocessing plant in France, ^{14}C is introduced directly to the atmosphere through a 100 m chimney (Fontugne et al., 2004), and at the Sellafield nuclear reprocessing plant in England, ^{14}C is released directly into the marine environment (Cook et al., 2004). While these types of releases still occur, they are miniscule in comparison with the quantities of ^{14}C released during the era of nuclear weapons testing. Nuclear fuel reprocessing currently produces only a small fraction of the natural total production of atmospheric ^{14}C .

Calibration of the ^{14}C Record

P J Reimer, R W Reimer, and M Blaauw, Queen's University Belfast, Belfast, UK

This article is a revision of the previous edition article by P.J. Reimer and R.W. Reimer, volume 4, pp. 2941–2950, © 2007, Elsevier B.V.

Introduction

^{14}C ages, or radiocarbon ages as they are also known, are calculated from the ratio of the radioactive carbon isotope ^{14}C to total carbon or one of the stable isotopes (^{12}C or ^{13}C) in the sample compared to a standard. This calculation assumes that the level of ^{14}C in the atmosphere has been constant since the time the sample grew or was formed. If that were the case, then no calibration would be needed. However, <10 years after the establishment of the radiocarbon dating method, discrepancies between radiocarbon and tree-ring ages were noted and potential mechanisms were discussed (de Vries, 1958). Such discrepancies are especially important when comparing records with a timescale based on radiocarbon ages with those based on other methods, such as layer counting or historical events, or for calculating rates of change.

The concentration of ^{14}C in the atmosphere at any given time depends on a number of factors including the strength of the geomagnetic field and the solar wind intensity, which influence ^{14}C production, and the uptake or release by the earth's carbon reservoirs, particularly the ocean (see [Causes of Temporal \$^{14}\text{C}\$ Variations](#) and [Variations in Atmospheric \$^{14}\text{C}\$](#)). Ocean surface water, which has partially equilibrated with the atmosphere, diffuses or sinks from the surface into the deep ocean where it is isolated from the atmosphere for hundreds or thousands of years (see [Thermohaline Circulation](#) and [Paleoceanography An Overview](#)). The carbon in the water has time to undergo radioactive decay before it is brought to the surface again through upwelling. This lower oceanic radiocarbon content means that samples formed in the ocean surface waters are on an average ~400 years older than samples formed in the atmosphere at the same time. This offset between the atmosphere and ocean surface age is referred to as the marine reservoir effect or marine reservoir age. In addition to natural causes of atmosphere ^{14}C variations, anthropogenic releases of fossil fuel and ^{14}C produced by nuclear weapons testing have altered the ^{14}C concentration in the atmosphere, biosphere, and oceans.

Thus began the quest for known-age samples and precise ^{14}C measurements to correct for the variations in atmospheric, and eventually oceanic, ^{14}C levels through what became known as radiocarbon calibration. The first high-resolution atmospheric calibration based on ring-counted *Sequoia gigantea* was published as both a calibration curve and a table of calendar and radiocarbon ages extending from 1000 to 1850 cal AD (Stuiver and Suess, 1966). Although the resolution and the precision were not as high as the most recent international calibration curve IntCal09, this was undoubtedly a remarkable achievement (Figure 1). Between 1966 and 1979, numerous radiocarbon calibration curves were built using various data sets, criteria for inclusion of data, and methods of combination or smoothing. The lack of standardization

created confusion when comparisons were made between calibrated ages from different curves. In 1979, an international workshop was held to establish a consensus calibration (Klein et al., 1982). Since then, an international working group has produced updates to the calibration curve on ~5-year intervals with the most recent internationally ratified curve, IntCal09, extending to 50 000 calibrated years before AD 1950 (cal BP) (Reimer et al., 2009).

Calibration and Comparison Records

Tree-Rings

Tree-rings are one of the best recorders of atmospheric ^{14}C concentration because many temperate tree species reliably form one ring each year. Trees incorporate carbon into their cell structure through the process of photosynthesis, which uses carbon dioxide from the atmosphere. While some compounds, such as lignin, are added to the cell structure of the living sapwood, the cellulose itself is formed during a single growth season. The wood from one or more tree-rings taken together is usually pretreated with acid and alkali to remove the mobile sugars, resins, tannins, and most of the lignin in a process known as the de Vries method, or, in some cases, either holocellulose or α -cellulose is chemically extracted from the wood (Stuiver et al., 1984). The pretreated samples are then radiocarbon dated. Because there is some small uncertainty in the actual calendar age of the wood used for the ^{14}C measurement, due to different ring widths for each year in a block of wood or to material lost to saw cuts, the term calibrated or 'cal' age is used rather than calendar age.

Tree-rings can be counted from a known felling date to give a calendar age for each ring, which can then be measured for ^{14}C content. However, to extend the calibration beyond the oldest living trees, a sequence of ring width patterns from wood taken from historical buildings and subfossil trees extracted from bogs or river gravels can be matched to construct a dendrochronological record (Figure 2). A number of tree-ring chronologies have been constructed including the Belfast Irish Oak chronology and the Hohenheim oak and pine chronologies. These chronologies are based on tens to hundreds of trees for any given year. For example, the Hohenheim Oak chronology has a mean replication of over a hundred trees per year (Friedrich et al., 2004). The robustness of these chronologies has been demonstrated through cross-checking between independently constructed chronologies.

Corals

Corals have been extremely useful for ^{14}C calibration, both for developing calibration curves specific to marine samples and for extending the atmosphere calibration with the use of a

Figure 1 The first atmospheric calibration curve (gray) as measured by Stuiver and Suess (1966) compared to the 2009 international calibration curve IntCal09 (black), both shown as one-standard deviation error envelopes.

Figure 2 An example of tree-ring width pattern matching for three pieces of Irish oak, which form part of the Belfast Irish Oak chronology. Arrows point to the same year on all three pieces of wood. Photograph courtesy of Prof. M.G.L. Baillie, Queen's University Belfast.

reservoir correction, which will be discussed in more detail in a later section. Reef corals have been shown to build their skeletons of aragonite (calcium carbonate) in isotopic equilibrium with the dissolved organic carbon in the ocean water where they grow. Like tree-rings, reef corals also have annual banding, which can be counted. Unfortunately, individual corals rarely live more than a few hundred years at most, and no long chronologies have been built. However, because uranium from seawater is incorporated in the calcium carbonate, the age of the coral can be measured independently by uranium series dating (^{238}U – ^{230}Th and ^{235}U – ^{231}Pa), and an uncertainty in the calendar age is calculated (see **U-Series Dating**). Potential problems exist with contamination in corals due to dissolution of the coral aragonite and recrystallization as calcite, potentially incorporating older or younger carbon. This is

primarily a problem with corals that have been exposed to freshwater due to changes in sea level or uplift of the coral reef. Checks on the amount of calcite in a sample are done with x-ray diffractions, and samples with quantifiable calcite of $>1\%$ are not recommended for calibration data sets (Reimer et al., 2002).

Varved Sediments

Varved (annually laminated) sediments can potentially supply calibration records through ^{14}C dating of macrofossils, such as Foraminifera or terrestrial material contained in the layers from marine and lake sediments, respectively (see **Varved Lake Sediments**; **Varved Marine Sediments**). The conditions under which the laminations form must be well understood and occur annually with high fidelity. Multiple cores need to be stratigraphically correlated, or dated marker events, such as volcanic tephra (see **Tephrochronology**), need to be present to ensure that there are no hiatuses in the deposition. Sediments are often not continuously varved from the present back through time, so they must be anchored by independent means such as wiggle-matching to the tree-ring curve (see section '**Calibration Methods**'). Uncertainty in the anchoring and in the varve counts needs to be quantified in order to provide reasonable error estimates on the independent age. Ideally, only fragile plant or insect macrofossils, which would not survive extended transport, are used for dating lake sediments for calibration records. At present, only the Cariaco Basin varved sediment record has been incorporated into internationally accepted calibration curves (Reimer et al., 2009).

Aragonite deposits in some varved lake sediments may also be ^{14}C and ^{238}U – ^{230}Th dated. These records could potentially be incorporated into a calibration curve. The ^{238}U – ^{230}Th age must be corrected for initial ^{230}Th , which increases the uncertainty of the age. As with marine samples, the ^{14}C reservoir corrections may vary with time.

Speleothems

Cave deposits known as speleothems (see **Speleothems**) hold the potential for providing near-atmospheric calibration records beyond the end of the tree-ring records as CO_2 (from the atmosphere or soil) is incorporated into the calcite or aragonite when it forms (Hoffmann et al., 2010). The speleothem age can be determined from U–Th dating although usually a growth model is used to provide ages along the axis of the speleothem, where the samples for ^{14}C dating are taken. As with aragonite, the U–Th age must be corrected for initial ^{230}Th . Uncertainties in estimating the fraction of carbon from rock weathering (^{14}C free or 'dead carbon') incorporated into the speleothem require a correction, which is estimated from the overlap with the tree-ring curve or through modeling using stable isotopes. Speleothems were not included in the IntCal09 curve but will be included in the planned update.

Nonvarved Marine Sediments

Nonvarved marine sediments have not been considered as 'calibration' records in the strictest sense because their time-scale is not independently derived. However, if there is a

plausible physical mechanism for a climatic connection, some of these records can be ‘tuned’ or tie-pointed to other timescales (see [Chronologies](#)) through correlation of climate proxies, such as $\delta^{18}\text{O}$, alkenone-derived temperature, varve thickness, or color to the $\delta^{18}\text{O}$ temperature record in ice cores or U-Th-dated speleothems. The uncertainty in the derived timescale must include the uncertainties in both records and in the match between the records (e.g., [Hughen et al., 2006](#)). The ^{14}C ages of planktonic Foraminifera from the Cariaco Basin and Iberian Margin records tie-pointed to the Hulu Cave speleothem timescale ([Bard et al., 2004](#); [Hughen et al., 2006](#)) contributed greatly to the extension of IntCal09 calibration curve to 50 000 cal BP.

Calibration Curves

The combination of ^{14}C data sets to form calibration curves has ranged from simple averages in given windows of time to the implementation of a stochastic model for the underlying radiocarbon calibration curve. The random walk model used in the 2009 IntCal calibration curves incorporates observations with independent errors in the ^{14}C age uncertainty and calendar age, including asymmetry resulting from accumulating counting errors, and allows for the covariance between observations ([Blackwell and Buck, 2008](#)).

Calibration curves have been constructed for the most commonly sampled carbon reservoirs – the atmosphere and the surface-mixed layer of the ocean. The underlying assumption is that local or regional differences from these curves are small compared to the uncertainty of the measurements. When this is not the case, a correction must be applied (see section [‘Problems and Uncertainties in Calibration’](#)). The Northern

Hemisphere atmospheric curve is based on mid-latitude tree-ring measurements as far back as these records are available and then relies on reservoir-corrected marine records. For the Southern Hemisphere, mid-latitude tree-ring ^{14}C measurements have been made, which provide a separate calibration curve for a limited period, which is extended with a random effects model that incorporates the potential variability in the offset. For the marine curve, there have been very few measurements of long calibration records for the Holocene, so the marine curve for this period has been modeled from a simple ocean–atmosphere box-diffusion model using the atmospheric curve as input. The portion of the Marine09 curve older than 10 500 cal BP is based on data from various ocean regions, which has been combined into a ‘global’ ideal curve by applying assumed constant regional reservoir corrections and then subtracting an average 405-year correction ([Reimer et al., 2009](#)).

Calibration Methods

Single Age Calibration

A radiocarbon age is conventionally given as a mean with one standard deviation, for example, 4560 ± 40 BP ([Stuiver and Polach, 1977](#)). Calibration, in the past, was done with a simple table of radiocarbon and calibrated ages for various standard deviations. However, as calibration curves were extended further back in time, it became impractical to publish complete tables. Graphical methods for calibration were also used. The calibration curve was intercepted by the radiocarbon age plus and minus one or two standard deviations to yield a corresponding calibrated age range or ranges ([Figure 3\(a\)](#)). This classical intercept method, while straightforward, does not

Figure 3 (a) An example calibration for a radiocarbon age of 4560 ± 40 BP using the classical intercept method. The radiocarbon age ± 1 and 2σ errors are drawn as lines intersecting the calibration curve, and the corresponding calibrated age ranges are shown as light gray and dark gray boxes, respectively. The IntCal09 calibration curve is shown as a one-standard deviation error envelope. (b) Calibration for the same radiocarbon age using the probability method. The 68% probability ranges are dark gray and the 95% probability ranges are light gray in both the radiocarbon and the calibration distributions.

Figure 4 Age estimators for the probability distribution of the radiocarbon age 4560 ± 40 BP calculated with the IntCal09 calibration curve including the classical intercept of the radiocarbon age with the calibration curve, the midpoint of the 95% calibrated age ranges, the median probability, and the moment or weighted average of the probability distribution.

include the full range of the uncertainty on the radiocarbon age and provides no information about the relative probability of multiple calibrated age ranges.

A probability density function (pdf) can be calculated, which retains information about the shape of the distribution. The pdf of the radiocarbon ages R around the mean radiocarbon age U is assumed normal with a standard deviation σ , such that

$$p(R) = \left(\frac{1}{\sigma(2\pi)^{1/2}} \right) \exp - \left[\frac{R - U^2}{2\sigma^2} \right]$$

where

$$\sigma^2 = \sigma_{\text{sample}}^2 + \sigma_{\text{curve}}^2$$

To obtain the probability density along the calendar axis, R can be replaced by the calibration curve function $g(t)$. By determining $g(t)$ for each calendar year t and transferring the corresponding probability of the distribution to the t axis, the probability density is transformed to calendar year dependency (Stuiver and Reimer, 1989). One and two standard deviation confidence intervals may be obtained from the age ranges, which contain 68 and 95% of area under the probability curve (Figure 3(b)).

The shape of the calibration curve at a particular point in time very obviously affects the resulting calibration. Often, the calibration results in broad calibrated age ranges; however, when a region of the calibration curve is very steep, then the resulting calibrated age ranges may be narrower than the radiocarbon age range. The calibrated pdf provides a complete description of the sample calibrated age but is difficult to use in calculations or graphics. Various attempts have been made to define a single number that represents the calibrated age of a sample. While some estimators, such as the moment (also called a weighted average) or the median (the calibrated age at which 50% of the probability falls before and 50% after), are

more robust than others (Telford et al., 2004), there is no good single estimator, and these may fall at relatively low probabilities (Figure 4). The intercept of the radiocarbon age with the calibration curve picks out only one, albeit the highest, of the peaks in probability but could shift significantly with only small changes in the radiocarbon age. Various Bayesian techniques have been developed to deal with the entire pdf in calculations, and these will be discussed later.

Wiggle-Matching

In situations where a time series of radiocarbon ages can be obtained, it is possible to improve the precision of the calibrated age considerably, especially if some of the ages fall on a steep portion or distinctive wiggle in the calibration curve. In its simplest form, a series of radiocarbon ages from tree-rings of known spacing can be moved along the calibration curve until a best match is achieved, classically calculated as the minimum of the weighted sum of squares of the difference. A good example of this is the wiggle-match dating of a series of 'royal' tombs of the Iron Age pastoralists in the High Altai region of Siberia. The dates of the tombs were a long-running controversy among art historians. Initial radiocarbon ages of some of the timbers used in tomb construction gave calibrated age ranges of several hundred years because of a plateau in the calibration curve ~ 800 – 400 BC. A relative chronology for the construction of the tombs was refined with a 'floating' dendrochronology (Marsadolov, 1996), but there was no fixed calendar date. A wiggle-match of ^{14}C ages of a single timber from the Pazyryk 2 tomb with bark attached was used to anchor the dendrochronology and provide a date for the tombs (Figure 5). While easily demonstrated, the uncertainty in the match using the classical statistics method is not rigorously determined, whereas Bayesian methods (see next section) provide a more robust estimate of uncertainty.

Figure 5 Wiggle-match of the Pazyryk radiocarbon ages versus tree-ring number to the IntCal09 calibration curve. The curve is plotted as a one-standard deviation error envelope, and the radiocarbon ages are given with one-sigma error bars. A bar marks the position of the bark relative to the radiocarbon samples.

The Bayesian wiggle-match gave a felling date for the timber from the Pazyryk 2 tomb of 301–282 BC at two standard deviations (Mallory et al., 2002, see also Kuzmin et al., 2004).

Similar wiggle-matches have been done to anchor floating chronologies for calibration data sets such as the match between the Cariaco Basin varved sediment record and tree-ring ^{14}C . Wiggle-matches, where the spacing in calendar time between ^{14}C -dated samples is not known, such as peat or sediment, can be done by finding the best fit within a physically reasonable range of sedimentation rates. Most of the progress in this area has been made using a Bayesian approach.

Bayesian Modeling

Prior information such as sample stratigraphy, varve counts, or marker events can be used to constrain the probability distributions and thus refine calibrated age ranges. For example, stratigraphic ordering requires that an upper sample be younger than a lower sample in a sequence. This *a priori* information can be used to constrain the original probability distributions so that the modified (or posterior) probability of the upper samples has less probability in the older ranges and more probability in the younger ranges, and vice versa for the lower samples (Figure 6). This is done formally by the application of Bayes's theorem of conditional probability to radiocarbon calibration (Buck et al., 1991). Bayesian calibration programs were initially designed for archaeological applications but can also be used to assess the reliability of stratigraphy or varve counting in paleoenvironmental studies. Recent research has focused on the theoretical framework necessary to apply Bayesian analysis to sedimentation rates, outlier

identification, and calibrated age-depth models (Blaauw and Christen, 2011; Bronk Ramsey, 2008).

Problems and Uncertainties in Calibration

Radiocarbon Error Estimates and Laboratory Offsets

Radiocarbon age errors are often given as the uncertainty resulting from the statistical nature of counting and do not include other possible errors that could result from, for example, sample preparation. An underestimation of the error will of course result in an underestimation of the calibrated age range. Interlaboratory comparison exercises on replicate samples have shown that for a number of laboratories, the errors are underestimated and also that small but significant offsets occur relative to consensus values (see Sources of Error). It is difficult to provide guidelines as to how much, if at all, the error should be increased in the absence of information from the laboratory.

Marine Reservoir Corrections

The actual difference between the atmosphere and surface ocean age (reservoir age) is not a constant but varies with time and location (see Causes of Temporal ^{14}C Variations). Regional upwelling of aged ocean water or input of freshwater necessitates a correction, ΔR , which to a first approximation is considered constant (Stuiver et al., 1986). ΔR can be calculated from the difference between the ^{14}C age of known calendar age marine organisms, such as mollusks, and the marine calibration curve value for that calendar age. Such samples must have

Figure 6 Probability distributions for two ^{14}C samples taken from a stratigraphic sequence with a simple calibration (black line) and with prior information (stratigraphic ordering) included using Bayes's theorem (solid purple). The radiocarbon ages of 4580 ± 40 BP (upper) and 4560 ± 40 BP (lower) are reversed as sometimes occurs in sediment records. The stratigraphic ordering forces the upper sample distribution toward younger calibrated ages and the lower toward older calibrated ages.

been collected before nuclear weapon testing (and ideally prior to the industrial era) because the underlying assumption that the atmosphere and ocean are in equilibrium is not valid during times of rapid atmospheric ^{14}C change. These samples are often difficult to obtain, particularly samples that are known to have been collected live or soon after death. In addition, different species of mollusk occupy different habitats and have different feeding patterns, which, in regions of carbonate rocks or freshwater input, can affect the ΔR value. ΔR is subtracted from the radiocarbon age, and the uncertainty is included in the radiocarbon age error before calibration with a marine calibration curve (Stuiver et al., 1986).

In many locations, ΔR has varied considerably with time because of changes in ocean circulation patterns or ice cover. Changes in ΔR have been documented through ^{14}C dating of marine and terrestrial pairs in archaeological sites or marine cores or by comparison of marine sample ages to well-dated tephra (Tephrochronology) layers. In regions where ΔR does vary with time t , it becomes somewhat of a circular argument to utilize a $\Delta R(t)$ value to correct a radiocarbon age for a sample without first knowing t . Regional marine calibration curves will undoubtedly be developed in the future to incorporate this information.

Freshwater Reservoir Corrections

Freshwater bodies generally reach equilibrium with the atmosphere relatively quickly, so lacustrine and riverine ^{14}C ages are calibrated with the atmospheric calibration curve. However, lakes and rivers, particularly in regions of carbonate bedrock, may have considerable reservoir ages (see ^{14}C of Plant Macrofossils). Moreover, old soil or peat carbon is often eroded into lakes. In volcanic regions, CO_2 released from subglacial eruptions or fissures in the lake bottom may contribute to a large

reservoir offset. ^{14}C measurements of surficial sediment samples or modern lacustrine plant material are used as a correction to the ^{14}C age before calibration, but the reservoir age may not have been constant over time. Lakes in newly deglaciated terrains, even in noncarbonate regions, may have an initial reservoir age due to the input of carbon that has been stored in the glacier since its formation, but the reservoir age tends to decrease as the water is replaced with groundwater and rainfall. ^{14}C analysis of terrestrial macrofossils or the identification of independently dated tephra layers is necessary to establish whether or not the reservoir age has been constant.

Mixed Marine and Terrestrial Samples

Animals that consume a mixed marine and terrestrial diet will contain carbon from both the atmospheric and marine reservoirs. When the tissue is radiocarbon dated, the marine proportion must be estimated and the calibration curve adjusted accordingly, or the results will be erroneous. The percent of marine carbon in the diet can be estimated in some cases from ethnohistorical documents, dental pathology, or stable isotopes, particularly of carbon and nitrogen. Much work has been done to determine the isotopic offset between the diet and various tissues in animals. Isotopic fractionation of carbon during photosynthesis causes an offset of the plant $^{13}\text{C}/^{12}\text{C}$ ratio from that of the carbon dioxide in atmosphere. Most plants follow one of two major photosynthetic pathways (C-3 and C-4), which have isotope fractionations that are distinctive, although CAMS plants may use either pathway. Additional fractionation also occurs when CO_2 dissolves in water, so that the $^{13}\text{C}/^{12}\text{C}$ of algae and phytoplankton falls between these two terrestrial plant values. It is therefore not possible to distinguish how much marine carbon has been consumed using carbon isotopes alone if both C-3 plants

(most temperate plants) and C-4 plants (tropical grasses including millet and maize) have been consumed. Nitrogen isotopes are fractionated with each step from primary production to consumption, so that marine samples, where there are multiple steps in the food chain, have higher $^{15}\text{N}/^{14}\text{N}$. By measuring both carbon and nitrogen isotopes in the sample, it is usually possible to estimate the marine carbon in the diet, although a complete analysis of food resources may be necessary to improve the uncertainty in the estimates. Where there are complicating factors such as freshwater fish in the diet, manuring of crops, or fractionation of nitrogen isotopes due to extreme heat or drought, measurement of other stable isotopes may be useful in separating the dietary sources.

Atmospheric Regional Effects

Despite the assumption, for calibration purposes, that the atmosphere is well mixed within each hemisphere, regional and local differences in atmospheric ^{14}C do occur and are designated as ΔR_a . Due to upwelling of old carbon in the Southern Ocean, the large ocean area and higher wind-driven air-sea mixing, the Southern Hemisphere atmospheric ^{14}C is strongly latitude dependent. At mid-latitudes, the Southern Hemisphere atmosphere is on average about 35 years older than the Northern Hemisphere, although this has varied from 0 to 100 years over the past two millennia (Hogg et al., 2009). In addition, the position of the intertropical convergence zone (ITCZ), the region of low pressure where the Northern and Southern Hemisphere trade winds meet, does not follow the equator and migrates seasonally as well as temporally. Thus, a plant growing near the ITCZ may utilize a mixture of Northern and Southern Hemisphere atmospheric CO_2 , which makes calibration uncertain. Other non-anthropogenic ^{14}C differences may be caused by higher ^{14}C production at high latitude and altitude, air-sea gas exchange near ocean margins in upwelling zones, CO_2 release from degradation of peat or soil, or outgassing of volcanoes or hydrothermal vents (see [Causes of Temporal \$^{14}\text{C}\$ Variations](#)). The first two of these have an effect of 10 or 20 years on the radiocarbon age of a sample at most, whereas the latter two can have a much larger effect in the immediate proximity of the source (e.g., Bruns et al., 1980; Walker et al., 2008).

There are also small offsets due to seasonal input of ^{14}C from the stratosphere into the troposphere. Plants growing early in the year may record a different ^{14}C level than those growing later in the year, which may be accentuated by climate changes. Small but significant differences, which would have an effect on calibration, have been measured between trees growing in Germany and those in Turkey during cold climate intervals (Kromer et al., 2001). An offset of 19 years has also been measured in herbarium specimens from Egypt (Dee et al., 2010). Fossil fuel usage may cause a localized depression in ^{14}C levels in addition to the general atmospheric ^{14}C decline from the beginning of the industrial era until the nuclear era, resulting in large calibrated age ranges.

Nuclear weapons testing resulted in high ^{14}C production in the upper atmosphere in the 1950s–1960s. Most of ‘bomb’ ^{14}C was input into the Northern Hemisphere and has gradually mixed throughout the atmosphere, but the distribution has not been globally uniform (Levin and Kromer, 2004).

Identification of the ‘bomb’ peak in sediments or peats provides a precise and useful time marker. Atmospheric and tree-ring ^{14}C measurements from various regions have been used to calibrate ^{14}C samples from the mid-1950s to the present. ‘Bomb’ calibrations have become increasingly useful in forensics and environmental applications. Mixing of ‘bomb’ ^{14}C into the ocean was even more variable making calibration impossible except in a few regions where records exist.

Future of Calibration

Floating European chronologies have recently been linked to the Hohenheim pre-boreal pine chronology by wiggle-matching both to the Huon pine chronology adjusted for the Southern Hemisphere offset (Hua et al., 2009). However, extending European chronologies through the last glacial period is a slow process due to the scarcity of trees growing in Europe at that time. Subfossil deposits of long-lived kauri (*Agathis australis*) in New Zealand offer the potential for tree-ring records back to the limit of radiocarbon dating at ~55 000–60 000 years ago. Even if these records cannot be firmly anchored to existing kauri chronologies extending from the present, they will provide useful information about variations in atmospheric ^{14}C (Turney et al., 2010).

Significant progress is being made on varved lake records. For instance, ‘missing’ varves in the Lake Suigetsu sequence are now being identified in the Lake Suigetsu 2006 Project by overlapping multiple cores and improved varve-counting techniques. ^{14}C dating of terrestrial macrofossils in the sediments may provide a reliable record of atmospheric ^{14}C levels for much of the radiocarbon age range and help to quantify the extent of reservoir changes in the marine records (Staff et al., 2010).

Other areas of research will have an impact on ^{14}C calibration. The extent of past marine reservoir changes is critical for the reliability of the marine calibration records and much work is being done to quantify these in many parts of the world. ^{14}C dating of organic material trapped in Ar–Ar (see [K/Ar and \$^{40}\text{Ar}/^{39}\text{Ar}\$ Dating](#))-dated volcanic deposits could provide essential atmospheric ^{14}C data as well. Independent dating of the geomagnetic excursions (see [Geomagnetic Excursions and Secular Variations](#)), such as the Laschamps event ~40 000 years ago, may provide a time marker for synchronizing ^{14}C records from different environments. Modeling of ^{14}C production based on paleomagnetic intensity data and records of other cosmogenic isotopes, such as ^{10}Be from ice cores, contributes to the understanding of ^{14}C variations (Laj et al., 2002; Muscheler et al., 2008), which may aid in selection of data sets for calibration curve construction.

Conclusions

Radiocarbon calibration curves have changed from relatively simple tree-ring-only compilations to the incorporation of different types of archives. This has required the development of specialized statistical tools and an improved understanding of ^{14}C distribution in the global carbon reservoirs. Although simple calibrations can result in imprecise ages owing to the

varying ^{14}C content of the atmosphere or ocean, events can be pinpointed more precisely by incorporating additional information such as stratigraphy in a Bayesian framework. As radiocarbon measurements on small samples have become more precise, so too has the need for consideration of regional reservoir effects. Extension and refinement of the calibration curves will require concerted effort by many individuals. While consensus ^{14}C calibration curves are an essential tool for comparisons between records, there is also the need to provide a sufficient means of recognition for the researchers who provide the individual calibration data sets.

Charcoal

M I Bird, James Cook University, Cairns, QLD, Australia

Introduction

Wood from an Egyptian tomb, linen used to wrap the Dead Sea scrolls, and a bread roll were among the first samples of known age used to test the radiocarbon dating technique. The bread roll was pyrolyzed to charcoal by the volcanic eruption of Pompeii in AD 79, and the radiocarbon date obtained on the sample was within error of the known age of the eruption (Arnold and Libby, 1949). This was the first ever radiocarbon date on charcoal, followed by a further dozen analyses of charcoal and charred wood from The Netherlands that suggested that charcoal could routinely produce reliable radiocarbon dates with minimal sample pretreatment (De Vries and Barendsen, 1954). Libby (1955) considered charcoal to be one of the most reliable materials for radiocarbon dating, and since that time, thousands of radiocarbon dates on charcoal have been produced by over 130 laboratories around the world. Radiocarbon dates on charcoal have contributed substantially to the chronological framework that underpins our understanding of human history and prehistory, as well as trajectories of change in the natural environment over the last 50 000–60 000 years.

In the last two decades, the ability to measure the radiocarbon activity of a few milligrams of carbon by accelerator mass spectrometry (AMS) (see [AMS Radiocarbon Dating](#)) has enabled the measurement of samples an order of magnitude smaller in size than was previously possible (see [Conventional Method](#)). This has not only allowed the dating of samples too small to date by conventional techniques, but has also extended the range of carbonized materials that can be dated to aerosol-sized 'black carbon' and individual biomarker compounds produced during combustion/pyrolysis (e.g., Reddy et al., 2002). As a result, radiocarbon dating of 'charcoal' is increasingly being used to support research into the biogeochemical cycling of carbon as well as the more traditional geochronological applications in archaeology and paleoenvironmental reconstruction.

'Charcoal': Definitions, Structure, and Chemistry

Pyrolysis accompanying the incomplete combustion of organic material produces a wide spectrum of particulate, carbon-rich, and generally O–H–S–N-poor compounds. This material is known by a variety of names including charcoal, microcharcoal, carbonaceous spherules, soot, fusain, elemental carbon, oxidation-resistant elemental carbon, microcrystalline graphite, black carbon, and graphitic black carbon. The very range of names used to describe this material reflects not only its compositional complexity but also its importance across a range of disciplines, each of which has evolved not only a terminology but also a set of methodologies for the analysis of this material and interpretation of the results.

In an archaeological and paleoenvironmental context, charcoal generally refers to macroscopic material resulting from the incomplete combustion of woody plant tissues ([Figure 1](#)). The

term 'charcoal' is widely recognized and hence it is used in this review, but an important conceptual development has been the recognition that 'charcoal' and the components that make up charcoal form part of a 'combustion continuum' (e.g., Masiello, 2004). At the low-temperature end of this continuum lies slightly charred biomass of low aromaticity, high reactivity, and comparatively large (mm to cm) size, while at the other end lie submicron-sized black carbon particles and a range of individual pyrogenic molecules, formed from gas phase condensation at high temperature and having high aromaticity and low reactivity ([Figure 2](#)). Macroscopic 'charcoal' lies at the center of this continuum and thus potentially contains a wide variety of components of variable reactivity.

The morphology and chemical composition of charcoal is initially controlled by the material that is pyrolyzed. Woody tissues are composed primarily of lignin and cellulose, cross-linked into a structure that is rigid and rich in polyphenolic compounds, while leaves contain higher proportions of non-structural material such as sugars and waxes. Most macroscopic charcoal preserved in the geologic record is derived from wood, and the open porous structure of woody tissues is often preserved intact after conversion of the wood to charcoal ([Figure 3](#)). The chemistry of charcoal is also dependent on the conditions of pyrolysis, with a general increase in carbon content and aromaticity along with a decrease in H/C and O/C ratios as temperature increases (Masiello, 2004). Black carbon forms from the condensation of polycyclic aromatic hydrocarbons into hydrogen-poor solid spheres generally <1 µm in diameter and as a result retains none of the structures of the pyrolyzed parent material (e.g., Gustafsson et al., 2001; [Figure 4](#)).

Franklin (1951) noted that the x-ray spectra of many pyrolyzed materials suggested the presence of microcrystalline graphitic carbon, and that upon heating to higher temperatures, microcrystalline graphite formed readily from some precursor materials and not others. She proposed the existence of 'organized' and 'nonorganized' components in most pyrolyzed material, with the proportion of each dependent upon the chemical structure of the starting material. Support for this model has come from high-resolution transmission electron microscopy, which has identified the presence of nanometer-scale domains of microcrystalline graphite in an 'amorphous' matrix in natural macroscopic charcoal fragments (Cohen-Ofri et al., 2005; [Figure 5](#)). This complexity and heterogeneity has significant implications for radiocarbon dating.

Charcoal Stability

The presumption of long-term stability of charcoal in the environment is based on several observations including the high degree of resistance of some charcoals to a range of oxidants (Bird and Gröcke, 1997; Skjemstad et al., 1996; Wolbach and Anders, 1989) and its preservation for long periods of time in the geologic record (Cope and Chaloner, 1980). It is

also known that charcoal is a significant component of many soils where it can persist for thousands of years (e.g., Hopkins et al., 1990; Pessenda et al., 2001) and can form a significant component of the 'inert' soil carbon pool (Lehmann et al., 2008).

However, evidence is accumulating that charcoal may not be as stable as previously supposed. A number of mass balance

studies have demonstrated significant loss of PC on decadal to centennial timescales (Bird et al., 1999a,b; Czimczik et al., 2005; Hammes et al., 2008) but not on annual timescales (Eckmeier et al., 2007; Major et al., 2009). Support for the degradation of at least some components of soil charcoal has also come from Glaser et al. (1998) who concluded that a proportion of the highly aromatic fraction of some humic acids may be derived from charcoal, and from evidence for the *in situ* production of humic acids from charcoal (Ascough et al., 2011a).

In addition to microbial degradation, it has also been shown that charcoal is susceptible to photooxidation, albeit at a slower rate than organic carbon (Skjemstad et al., 1996), and experiments have demonstrated that exposure of black carbon to normal atmospheric concentrations of ozone leads to rapid surface oxidation, in turn rendering black carbon particles soluble in distilled water (Chughtai et al., 1991).

Two main factors during production have been shown to influence the susceptibility to chemical oxidation of charcoal and by inference are likely to be of importance in determining the stability of charcoal in the natural environment. The first is the efficiency of the pyrolysis process, with high-temperature and low-oxygen availability favoring the formation of carbon-rich charcoal containing little labile organic matter. Such charcoals have a high carbon content (>75%) and a high resistance to chemical oxidation. The second is the density of the organic matter and hence the surface area of the charcoal produced by

pyrolysis. High-density woody material, with comparatively low surface area, yields charcoal that is more resistant to chemical oxidation than charcoal produced from lower density organic matter, such as leaves ([Bird and Gröcke, 1997](#)).

While it is known that charcoal exhibits a wide range of behaviors when subjected to chemical or thermal oxidation, the variations in charcoal chemistry that must underlie these behaviors has received little attention. The emerging evidence suggests that while there may well be some highly refractory carbon present in most charcoal, a significant proportion may be labile and reactive on comparatively short timescales (e.g., [Ascough et al., 2011b](#)).

The significance of charcoal stability for radiocarbon dating has been underscored by an intensive study of the Nauwalabila I archaeological site in Northern Australia. Attempts to date charcoal at depth in the sequence using a range of pretreatment protocols were completely unsuccessful due to pervasive alteration and contamination of the charcoal as a result of oxidative degradation and exposure to a fluctuating groundwater table ([Bird et al., 2002](#)). In addition, comparison of modern and ancient charcoal from archaeological sites in Israel using an extensive suite of analytical techniques has demonstrated that the fossil charcoals have undergone

Figure 5 High-resolution transmission electron micrograph of modern charcoal (*Ceratonia*) showing the presence of 'organized' domains of microcrystalline material in an amorphous matrix, as discussed by [Cohen-Ofri et al. \(2005\)](#). The image was taken by Dr. Ronit Popovitz-Biro, Department of Chemical Infrastructure, Weizmann Institute of Science, Israel. Scale bar is 5 nm in length.

significant chemical alteration, in turn raising the possibility that significant contamination could have been introduced during the process of alteration ([Cohen-Ofri et al., 2005](#)).

Charcoal Contamination

The main prerequisite for the reliable measurement of radiocarbon activity is the material being analyzed. If charcoal will degrade, as appears to be the case, this must also mean that there is potential for contamination that is not easily removed, as contaminants may have been involved in irreversible reactions with the charcoal surface. There are several mechanisms by which charcoal may be contaminated to the extent that the reliability of a radiocarbon measurement on the sample may be compromised:

- (i) Charcoal has a large internal and external surface area and acts as a sorbent for a range of organic and inorganic

compounds, with 'activated' carbon being an extreme example (Gustafsson et al., 2001). During what is often millennia between the formation of charcoal and its sampling for analysis, charcoal in the natural environment will have been exposed to soil solutions containing a range of organic compounds and some, including carbohydrates, amino acids, and phenolics, have been shown to adsorb readily to natural charcoal (Pietikäinen et al., 2000). These compounds may be loosely bound but some may undergo irreversible reactions with functional groups on the charcoal surface. pH is likely to exert a significant control on both the degradation and contamination of charcoal (e.g., Braadbaart et al., 2009).

- (ii) The capacity of charcoal to adsorb metabolizable compounds, coupled with its porous nature, makes it a suitable substrate for microbial colonization, and several studies have demonstrated enhanced soil microbial activity associated with charcoal (e.g., Zackrisson et al., 1996). This cycling of carbon between the charcoal and the local environment can continue long after the initial formation of the charcoal and a portion of this material may be irreversibly incorporated in the charcoal.
- (iii) Combustion of organic matter leaves a residue of ash, the main component of which is commonly CaO (lime) along with oxides of other cations. Over time, this material becomes hydrated and is ultimately converted to carbonate (Demeyer et al., 2001). Calcium carbonate is often intimately associated with charcoal in alkaline environments and represents an additional potential source of carbon contamination. In some environments, iron carbonate (siderite) may also be formed during pedogenesis, and as this mineral is relatively insoluble in acid, it may not be readily removed by some pretreatment techniques designed to eliminate contaminants (Hatté et al., 2001).

Sampling Charcoal for Radiocarbon Dating

The recognition that charcoal forms part of a 'combustion continuum' means that there is no single technique for sampling charcoal for radiocarbon measurement. Sampling of macroscopic charcoal, from archaeological sites and soil/sedimentary sequences is relatively straightforward. Fragments can be handpicked from the sedimentary matrix, wrapped in solvent-washed aluminum foil, and sealed in a labeled plastic bag. Provided a modicum of care is exercised in sampling so that no foreign contaminants are introduced, and provided the stratigraphic context of the sample is recorded, the sample can then be dated using radiocarbon. Smaller fragments of charcoal, down to a few hundred microns in diameter, can be concentrated by dry or wet sieving. Charcoal retained on the sieve can be further concentrated by swirling the material in water and decanting off the charcoal and organic particles, which remain in suspension longer than the heavier mineral material. Final purification of a charcoal separate can then be achieved by handpicking a few milligrams of charcoal under a binocular microscope. At some particle sizes, determined by the importance of the sample and patience of the analyst, handpicking of charcoal becomes impractical and chemical

treatments are required to concentrate sufficient charcoal for dating as discussed in the following section.

Pretreatment of Charcoal for Radiocarbon Dating

Modern AMS target production lines can potentially yield finite radiocarbon dates on charcoal of ~55 000 years for a 1 mg target (Bird et al., 1999a,b; Pigati et al., 2007), but this requires that samples be completely free of carbon not indigenous to the charcoal. Chemical pretreatments for charcoal can be classified into two broad categories, the first applied to macroscopic charcoal physically separated from a sedimentary matrix and the second aimed at chemically or thermally isolating fine charcoal from other organic matter in a sedimentary matrix. The aim of all these pretreatments is to remove both younger and older organic as well as inorganic carbon from the charcoal so that the measured radiocarbon activity is directly related to the radiocarbon activity of the sample at the time it was pyrolyzed.

There are generic precautions that should be taken to minimize laboratory contamination, regardless of pretreatment strategy. Thus all pretreatment steps should be carried out in either a laminar flow cabinet, in a HEPA-filtered clean laboratory, or in capped vials with all vessels and implements pre-cleaned either by combustion overnight at 550 °C (Pyrex), 880 °C (quartz) or by washing with a hot solution of 0.1 M $K_2Cr_2O_7$ in a 2 M solution of H_2SO_4 . All water used should be as pure as possible.

Acid-Alkali-Acid

De Vries and Barendsen (1954) first used combinations of acid and alkali extraction as a pretreatment for radiocarbon measurement of 'charred wood' and demonstrated that in some cases acid-soluble material was considerably younger than either the alkali-soluble or insoluble fractions. These results indicated that charcoal could be contaminated by younger carbon, but the contamination could apparently be easily removed. The acid wash is designed to remove 'fulvic acids,' and the alkali wash is designed to remove 'humic acids.' Recognition that alkaline solutions will take up atmospheric carbon dioxide (and hence ^{14}C) that might then be irreversibly incorporated into the sample led to the addition of a final acid wash designed to eliminate this possibility.

This general protocol, which is widely used for many organic sample types, has evolved into the acid-alkali-acid (AAA) pretreatment, although, in practice, the actual protocol employed differs substantially between laboratories. The AAA technique is widely used for charcoal but has also been used with success on cremated bone remains (Nakamura et al., 2010). The acid used is generally HCl but the base may be NaOH, NH_4OH , or KOH, while the strength of these solutions varies between 0.1 and 1 M, the temperature from ambient to boiling, and the time from less than 1 h to 1 day, with the possibility of multiple extractions, particularly at the alkali step. In part, this flexibility in application is required because of widely differing responses of charcoal to the procedure, as the alkali extraction step, in particular, may result in anything from zero to complete sample dissolution.

The addition of an initial HF or HF/HCl wash to remove silicates or aqua regia ($\text{HNO}_3 + \text{HCl}$) to remove iron minerals and thereby expose protected organic contaminants to the reagents and the replacement of the final HCl wash with either H_2SO_4 or an acid oxidation reagent such as nitric acid have been proposed to improve the performance of the AAA pretreatment (e.g., Gillespie et al., 1992; Haesaerts et al., 2010; Hatté et al., 2001). An additional improvement to the AAA pretreatment has been the use of a range of techniques including Raman and Fourier transform infrared spectroscopy to screen charcoal samples for radiocarbon measurement and monitor the removal of humic acid contamination through successive steps of the AAA procedure (Alon et al., 2002; Rebollo et al., 2008).

Acid-Base Oxidation with Stepped Combustion

In order to address the issue that the AAA pretreatment does not always remove contamination from charcoal to a consistently low level, Bird et al. (1999a,b) developed a more rigorous pretreatment for charcoal samples. The acid-base oxidation (ABOX) pretreatment is based on methods developed to quantify 'elemental carbon' in sediments (Bird and Gröcke, 1997; Wolbach and Anders, 1989) and is similar to AAA but replaces the final acid wash with an acid oxidation step designed to chemically oxidize any contaminants tightly bound to the charcoal surface.

Handpicked fragments of charcoal are crushed in a mortar and pestle and a 10–200 mg aliquot is weighed into a 50 ml capped polypropylene centrifuge tube. 20 ml of 6 M HCl is added to the tube, which is then capped and left to stand for an hour, after which it is centrifuged and rinsed twice. If the sample contains appreciable mineral impurities, a 1:1 mix of concentrated HCl and HF can be used in place of a simple acid wash to dissolve any mineral phases. 30 ml of 1 M NaOH is then added to the tube, which is left to stand for 30 min before rinsing.

Thirty milliliters of acid-dichromate oxidant solution (0.1 M $\text{K}_2\text{Cr}_2\text{O}_7$ in a 2 M solution of H_2SO_4) is added, followed by heating to 60 °C for 14–24 h. The oxidation time is a compromise required to ensure that sufficient sample material is left for further analysis. With larger samples or more dense charcoal fragments, the oxidation time can be increased to 72 h or longer. Following completion of the oxidation step, the sample is washed several times with hot water with fine particles that remain in suspension for longer than 5 min also discarded, and then the sample is dried and weighed.

The concept of stepped combustion as developed by Bird et al. (1999a,b), derives from thermal techniques for quantifying fine 'charcoal' in a range of environmental materials including aerosols (Cachier et al., 1989) and sediments (e.g., Gustafsson et al., 2001) and can be applied to raw, AAA, or ABOX pretreated samples. Rather than simply combusting the total sample at high temperature, heating at 330–360 °C in an oxygen atmosphere results in the combustion of any organic contaminants still adhering to the charcoal surface or added during sample handling. A second combustion step at 650 °C initiates the combustion of the charcoal and a final combustion step at 850–900 °C leads to the complete combustion of the uncontaminated 'core' of the sample. A graphite target for

radiocarbon determination can be made from the CO_2 produced during each combustion step.

As thermal oxidation can be expected to remove less resistant phases first and work progressively from the outside to the interior of the particles, any contaminants remaining after the sample pretreatment will be combusted during the low-temperature step, and the 'reliability' of the radiocarbon measurement can be assessed by the coherence of the results from the high-temperature steps. In practice, the low-temperature fraction is usually contaminated to some degree and can simply be discarded.

Tests on raw, AAA, and ABOX pretreated samples of known age and known 'infinite' age have demonstrated that acid-base oxidation with stepped combustion (ABOX-SC) out-performs other protocols by reducing contamination to consistently low levels of ~0.1pMC (percent modern carbon) or better, equivalent to an 'age' of approximately 60 000 years BP and meaning that under favorable conditions, reliable dates up to ~58 000 years BP are achievable (Bird et al., 2003). Several studies have now demonstrated that the ABOX pretreatment provides reliable decontamination and can perform better than AAA pretreatments, particularly for samples older than 40 000 years (e.g., Douka et al., 2010; Higham et al., 2009a,b; Turney et al., 2001).

Other Techniques

The ABOX-SC pretreatment is very harsh and often results in large losses of sample material. Likewise, in many instances, the alkali step of the AAA pretreatment may result in virtually complete dissolution of charred samples (Hedges et al., 1989; Rebollo et al., 2008). A recently developed alternative technique is the use of catalytic addition of hydrogen to reductively separate labile and refractory PC components. This is achieved via pyrolysis at up to 550 °C under high H_2 gas pressures, known as hydrogen pyrolysis (hypy). Hypy results in total reductive conversion and removal of common PC contaminants, such as cellulose and humic substances, isolating a chemically consistent, highly aromatic component from both macroscopic charcoal and fine charcoal from complex matrices such as soils (Ascough et al., 2009, 2010). In this regard, hydrogen pyrolysis offers advantages as a ^{14}C pretreatment, as it is possible to effectively degrade compound classes routinely targeted for removal without unnecessary loss of the resistant indigenous charcoal component of interest for dating, thus minimizing sample loss.

Low-temperature oxygen plasma ashing has also shown promise as a technique for decontaminating charcoal prior to radiocarbon dating. Plasma ashing has been demonstrated to be rapid and controllable, and to perform as well as the AAA technique in decontamination. Because the technique is limited to the sample surface accessible to the plasma, it may not always remove all contamination but provides a viable alternative in cases where more aggressive techniques cannot be used because of small sample size (Bird et al., 1999a,b).

Radiocarbon Dating of 'Fine Charcoal'

Many techniques for the isolation and quantification of products of combustion too small to be separated by hand have been developed over the last decade and radiocarbon measurements of these samples are increasingly being used for the

purposes of dating and source attribution. Source attribution commonly relies on the fact that, unlike charcoal derived from biomass burning, fossil fuel-derived combustion products do not contain radiocarbon. These techniques can be categorized into those aimed at the isolation of particulate material and those that isolate individual compounds produced during combustion. For recent reviews of these methods, see Hammes et al. (2007), Masiello (2004), and Schmidt et al. (2001).

Techniques aimed at particulate isolation fall broadly into two groups, using both an acid treatment to remove carbonates and an HF treatment (used as required) to remove silicates that can protect organic matter. Thermochemical techniques utilize the fact that organic matter oxidizes at a lower temperature than charcoal. Thus, any carbon surviving after heating in an oxygen-containing atmosphere to a temperature of generally 340–375 °C for a predetermined time is considered to have derived from burning (e.g., Gustafsson et al., 2001). The main issue with these techniques, in the context of radiocarbon measurement, is the possibility that the thermal treatment leads to the charring of some organic matter that, in turn, can ‘fix’ contamination into the sample.

Wet chemical techniques use a variety of chemical oxidants including potassium dichromate, potassium permanganate, sodium hypochlorite, nitric acid, or photochemical oxidation using UV-radiation (e.g., Eckmeier et al., 2009; Hammes et al., 2007), at a range of temperatures for a range of times to oxidize organic material. The main issue with chemical oxidation is the possibility of sample loss through the procedure, which is important only if quantification of the material is required.

Compound-specific techniques use either solvent extraction or oxidation to isolate compounds known to derive from combustion, usually polycyclic aromatic hydrocarbons (Gustafsson et al., 2009; Reddy et al., 2002), levoglucosan (Elias et al., 2001), or benzene carboxylic acids (Glaser et al., 1998). These are then separated and quantified by high pressure liquid chromatography or gas chromatography–mass spectrometry. Advances in AMS that now enable on-line, continuous-flow radiocarbon determinations of individual compounds separated by gas chromatography are likely to lead to an increase in the analysis of these compounds in the future for both geochronological and source attribution applications.

In the context of radiocarbon dating, the choice of any of the above techniques is dependent on the application. If geochronology is the prime aim, then a rigorous protocol combining wet chemical and thermochemical techniques, such as ABOX-SC, is most appropriate, whereas if quantification for the purposes of source attribution is the aim, then a ‘gentler’ protocol should be adopted.

Conclusion: Interpretation of Radiocarbon Dates on Charcoal

Discussion in the preceding sections has highlighted that ‘charcoal’ should be thought of as part of a combustion continuum, the components of which range from macroscopic to molecular and from refractory to comparatively labile. Assuming that the fundamental issue of contamination has been dealt with through appropriate pretreatment and analytical protocols,

there remain several potential issues in the interpretation of the radiocarbon measurement of a sample. These relate to the nature of the charcoal isolated for analysis, the context from which the sample was obtained, and the purpose for which the analysis was made.

If the purpose of the measurement is to obtain the age of an event then the radiocarbon ‘date’ must be calibrated to calendar years. Charcoal produced from the combustion of terrestrial biomass produced from photosynthetic fixation of atmospheric CO₂ is not subject to an inherent reservoir effect, and hence calibration to calendar years can be based on the atmospheric calibration curve (see [Calibration of the ¹⁴C Record](#)). However, Gavin (2001) found that radiocarbon dates on charcoal derived from forest fires on Vancouver Island were 180–670 years older than the known age of the fires, and Nakamura et al. (2010) found macroscopic charcoal to be older than cremated bone, in both cases due to the inbuilt age of the wood prior to combustion. Inbuilt ages in charcoal of a few decades are likely to be common as wood takes time to grow, and this needs to be considered when interpreting radiocarbon dates on charcoal ([Figures 6 and 7](#)).

Radiocarbon dates on macroscopic charcoal are likely to provide a reasonably accurate estimate of the time of burning in most cases, but often such dates are used to infer the timing of a separate event by stratigraphic association. In a case where charcoal is clearly associated with a hearth, the association between the age of formation of the charcoal and the timing of human use of the hearth is fairly direct. In many instances, this is not the case, and the age of an event is inferred simply from a stratigraphic association between charcoal and an artifact or change in the composition of a sedimentary sequence. This becomes increasingly difficult to substantiate as the size of the charcoal decreases for two reasons:

Figure 6 Archaeological excavation at Pedra Furada, Capivara National Park, Brazil. A mid-Holocene hearth associated with abundant charcoal fragments is visible in the center bottom of the frame 1.5 m below the modern ground surface. Charcoal fragments are also visible in the walls of the excavation as black specks. Photograph: Michael Bird.

Figure 7 A cleaned eroding fluvial section that revealed a cross-section of a Norse charcoal production pit, in Eyjafjallsveit, Southern Iceland. The pit was cut through the Eldja AD 935 tephra and after its use was covered with eolian material from natural soil accumulation and eventually the tephra fall of Hekla AD 1341. Radiocarbon dating of the basal charcoal fill places the use of the pit into the late twelfth to thirteenth centuries AD. Photograph by Mike Church, with permission.

- (i) Physical bioturbation after deposition can result in the vertical translocation of material, and this becomes more likely as charcoal particle size decreases and sediment particle size increases. The importance of this process is site specific as the good agreement between dates on coarse charcoal and organic carbon from the equivalent levels of soil profiles in the Amazon Basin has indicated no large-scale translocation (Pessenda et al., 2001), while other studies have indicated that millimeter-sized charcoal can be redistributed vertically over several meters in coarse sandy sediments (Bird et al., 2002).
- (ii) It is likely that the more refractory components of charcoal, with a longer lifetime in the environment, are transmuted into finer size fractions as charcoal is degraded. Fine particles are more likely to be transported by wind or water over long distances before deposition in the location from which they are ultimately collected. An extreme example of this has been provided by Dickens et al. (2004) who isolated 'graphitic black carbon' from subrecent marine sediments of the West Coast of North America and demonstrated that the material was almost entirely depleted of radiocarbon, meaning that the 'age' of the material bears no relationship to the age of deposition in the sediments.

Substantial advances have been made in the development of techniques for isolation of charcoal for radiocarbon analysis, most of which are underpinned by the development of AMS measurement techniques and hence the ability to analyze milligram quantities of material. This has enabled a substantial increase in the types of material that can be measured and the natural matrices from which charcoal can be isolated for measurement. However, the interpretation of radiocarbon measurements on charcoal still relies fundamentally on a thorough appreciation of the methodological issues and complications that are specific to the purpose for which the

measurements are being taken and that are also often specific to an individual sample. Radiocarbon dating of charcoal is increasingly going to rely on the application of a suite of additional chemical and spectroscopic techniques to check the suitability and purity of each sample prior to analysis (e.g., Alon et al., 2002; Cohen-Ofri et al., 2005; Rebollo et al., 2008), on cross-comparison with results obtained using other sample types (Haesaerts et al., 2010; Nakamura et al., 2010), and on geochronological techniques (e.g., Turney et al., 2001).

Glossary

Aging or rejuvenation: Shift in apparent radiocarbon age caused by an anomalously low (aging) or high (rejuvenation) ¹⁴C content of the original carbon. One of the fundamental assumptions underlying radiocarbon dating is that the material being dated was originally in equilibrium with the contemporary atmosphere and drew its carbon (and hence, its ¹⁴C) directly from the atmospheric 'reservoir.' However, if the material was formed in an environment which had a different ¹⁴C content to the atmosphere, then its radiocarbon age will be higher (aging) or lower (rejuvenation) than that of contemporary wood, depending on whether its carbon reservoir contained less (see 'hard water effect') or more (see 'bomb carbon') ¹⁴C than the atmosphere.

Bomb carbon: This expression refers to the significant quantity of ¹⁴C that was injected into the atmosphere by nuclear weapons testing between 1945 and the mid-1970s. The increased activity reached its peak around 1963; atmospheric ¹⁴C reached twice the normal level in the Northern Hemisphere and increased by about 60% in the Southern Hemisphere. It has since decreased to about 10% above 'prebomb' levels, due mainly to the exchange of CO₂ between the atmosphere and the oceans.

Hard water effect: The 'hard water effect' refers to the situation in which the radiocarbon age of fresh water (or organisms living in the water) in contact with limestone (calcium carbonate) can be increased by the dissolved carbonate in the water. As the limestone contains no ¹⁴C, the effect is to dilute the concentration of the ¹⁴C in the incoming CO₂.

Introduction

Until the late 1980s, the majority of dates for lacustrine or palustrine paleoclimatic studies were obtained by beta-counting of samples from organic lake muds or bulk peat sediment. However, since then, the preferred strategy is to date plant macrofossil material by accelerator mass spectrometry (AMS) (see [AMS Radiocarbon Dating](#)). This is partly because AMS offers the possibility of dating a much higher level of stratigraphic resolution (since it is possible to obtain dates on very small samples of material) and partly because of the widely held view that AMS dates on plant macrofossils are inherently more reliable than those obtained from the sediment matrix. In this case, the source of the carbon is known and therefore should not be composed of heterogeneous material that could be of different ages. In general, no account has been taken from plant macrofossils that may be species-dependent or that the plant macrofossils themselves may be redeposited. Consequently, inconsistencies even within the plant macrofossils chronologies are still common. This suggests that the choice of the appropriate material is not trivial and requires serious investigations.

Many studies on terrestrial paleoclimatic records aim to address the Last Glacial–Holocene transition. The characterization of this transition is mostly based on lacustrine or palustrine records. Establishment of a reliable and accurate chronology remains one of the major challenges in such an environment and time-slice. Indeed, because of the variations in the amount of ¹⁴C in atmospheric CO₂, this means that the measured amount of ¹⁴C is not linearly related to age, and the aging is highly critical.

We consider here plant macrofossils accounting for the context from which they are extracted. We then go deeper in the difficulties, from the archaeological context to aquatic

environment. Finally, we give some reminders about sampling, storage, and pretreatments of samples, and inherent possible contaminations.

Archaeological Contexts

In Quaternary studies, archaeological contexts are also an important area where plant macrofossil studies are of great importance. In archaeology, establishment of human evolution chronology is a key issue. Dating support has to be related without ambiguity to human life, industry, or art. Charcoal in a foyer can be linked to a human fire but not directly to the cave paintings drawn just above on the cave walls. A small amount of charcoal on the painting itself would give the date of the work. Besides charcoal, olive pits as food residues, plant leaf as basket component, and wood as timber are dedicated plant support for the ¹⁴C dating of human evolution. Nevertheless, even when directly related to human activity, ¹⁴C geochronology is not without risk.

'Old Wood' Effect

Quaternary scientists have long recognized the problem of the 'old wood' effect in radiocarbon-dating charcoal and wood samples, the age of which may be hundreds of years older than expected. This is particularly true for long-lived tree species such as oak and juniper. Every year, tree growth adds woods to the outside part of the trunk. The date measured on heartwood may be already many centuries old by the time the tree was cut down. An ideal material to date, if available, would be twigs of such trees as hazel or wicker willow that can

integrate 5 years at the worst. Another difficulty is that of possible time-lags between felling and final deposition. The timber may have had an extensive history of use and reuse. The date we are measuring is the death of the tree and not its last use.

Volcanic Area

Volcanic areas may be subjected to atmospheric CO_2 dilution by magmatic CO_2 . Since, the magmatic CO_2 is ^{14}C -free, this results of a ^{14}C dilution in plants of the surrounding areas (Cook et al., 2001; Pasquier-Cardin et al., 1999). A dilution by more than 85% has been observed in Mammoth Mountain, CA, in 1997. ^{14}C activity measurements can then be used as a way to track changes in volcanic activity. However, plant macrofossils inherit this dilution leading to an important artificial radiocarbon aging which can be as small as 200 years or up to 20 000 years. As volcanic activity is highly variable, it is thus really difficult to evaluate the magnitude of the aging. Using coupled $\delta^{13}\text{C}$ – ^{14}C measurements, Pasquier-Cardin et al. (1999) showed the way to evaluate the dilution ratio for volcanoes where clear ^{13}C enrichment in plant has been evidenced in Azores. Garnett and Billett (2007) follow a similar approach in Tyrrhenian Sea.

Tephra records can be also a partial solution to the dating problem facing peat–climate studies. The techniques of wiggle-matched radiocarbon dates and tephrochronology have been used in combination to obtain accurate and precise age estimates for prehistoric tephra and hence for peat layers (Molisso et al., 2010; Pilcher et al., 1996).

Soil and (Dry) Sediment

Scientists face new supplementary complications when drilling or coring for paleoclimate studies into soil or sediment. Indeed at the opposite of archaeological sites where human occupation layers are relatively well defined, no artifacts are present in the soil or sediment to fix the limits of the different units. Major units are often well described by color or major texture changes but within these units, laminated smaller layers are very rare. Few proofs of *in situ* fossilization without any further reworking are present. In nonaqueous and well-oxygenated environments, very rare large macrorests subsist to diagenesis. The tender part of the leaf, twig, and trunk rapidly disappears through bacterial activity. Only resistant parts of the superior plant can be found some thousands years later. This is the case of phytoliths (small silicate bodies produced in abundance in the tissue of most of the grasses), pollen and, on occasion, of seeds.

Bioturbation and Mechanic Disturbance

Whatever the sediment, action of roots, animal burrows, water and fine grain illuviation can distort the original record and even upward and downward movement might displace the target macrorests. The largest uncertainty with the macrofossil sample is ‘is the macrorest in place? or did it move upward or downward?’ In some lucky cases, some fragile seeds might

resist diagenesis and can be used as a reliable support for ^{14}C dating. In a moving environment, the fragile part of the macrorest is destroyed. Its presence proves the *in situ* fossilization. This is the case of birch seeds surrounded by a fragile sheath which presence attests that the macrorest was not subjected to a displacement posterior to its fossilization.

Phytoliths

Phytoliths are increasingly used for isotopic studies performed on organic matter linked to the silicate skeleton building (Hodson et al., 2008; Kelly et al., 1991, 1998; Smith and Anderson, 2001; Smith and White, 2004). Phytoliths trap trace amounts of organic carbon (0.09–1.3 wt%) that is encased in silica (Mulholland and Prior, 1993). The very small amount of carbon now required for a ^{14}C measurement can be used as ^{14}C dating support if it is associated with the highest control of the blank quality (Santos et al., 2010).

Nevertheless, their shape (often needles) and their high resistance toward diagenesis is not an advantage to check the *in situ* position without reworking of the chosen phytoliths in the section. This can be really problematic when a forest has replaced the savanna, the former having an extended and strong rhizosphere.

Pollen

Because many continental paleoclimatic studies are based on pollen assemblages, it appears judicious to directly use pollen grains in support of ^{14}C dating. However, very few ^{14}C datings are performed on pollen grains themselves (Long et al., 1992; Mensing and Southon, 1999), most are performed on pollen concentrate from sediment (Brown et al., 1989, 1992; Kilian et al., 2002; Piotrowska et al., 2004; Zhou et al., 1997), and the results are highly variable.

Based on pollen concentrates, Zhou et al. (1997) succeeded in obtaining a consistent chronology in paleosols and peat from the loess/desert transitional belt in China. However, pollen concentrates from loess or sand samples appear to provide ages that are either too old or too young. Zhou et al. (1997) observe that on the one hand, pollen are badly preserved in dry environments like sands, and on the other hand, reworked pollen are included in pollen concentrates. This reworked pollen can be either older (fossilized) spore pollen that could be transported with dust prior to sediment deposition or younger pollen transported through hydrological or agricultural activities. In Lake Baikal, Piotrowska et al. (2004) succeeded in establishing a good chronological framework based on concentrate pollen carried out using chemical treatment, microsieving, and heavy liquid separation.

At Lake Goszcz (Poland), Kilian et al. (2002) did not succeed in establishing a coherent temporal framework based on concentrate pollen ^{14}C dating, whereas ^{14}C dating on superior plant macrofossils (Goslar et al., 1995) provided reliable chronology. Indeed, all pollen concentrate samples showed an aging that was caused by the presence of the selected fractions of some resistant phytoplankton affected by the ‘hard water effect.’

Even with manually separated pollens, some problems remain. Indeed, this precise and laborious method (5000 of

spruce or 10000 pollen grains of pine to obtain 70 μg of carbon) does not exempt the sample from the possibility that some of the pollen grains can be reworked. Mensing and Southon (1999) demonstrate incorporation of older pollen grains in lacustrine sediment due to erosion from near-shore sediments due to Lake Moran (California) level fluctuation. They arrived at the same conclusion for marine sediments of the Santa Barbara Basin. This example of old pollen incorporation may be extended to most of lacustrine or palustrine environments linked to moraines and continental ice sheet melting (e.g., Great Lakes, North European lakes, Russia), where water inflow drains old sediments that may contain very old pollen grains.

Lacustrine and Palustrine Records

Many studies on terrestrial paleoclimatic records aim to address the Last Glacial-Holocene transition. The characterization of this transition is mostly based on lacustrine or palustrine records. Establishment of a reliable and accurate chronology remains one of the major challenges in such an environment and time-slice. Indeed, as the variations in the amount of ^{14}C in atmospheric CO_2 , means that the measured amount of ^{14}C is not linearly related to age, the aging is highly critical. This article now turns its focus on plant macrofossils available in these humid environments, from algae to superior plant macrofossils.

Algae and Aquatic Moss Macrofossils

Aquatic cells photosynthesize subaquatically and hence build carbon from dissolved inorganic carbon (DIC) into their cellular material, so they reflect the ^{14}C : ^{12}C ratios of the water from which they grow. The DIC is influenced by (1) exchange with the atmospheric CO_2 reservoir, (2) decomposition of organic matter, (3) dissolved carbonate from surrounding

limestone catchments, and (4) residence time of lake or peat-bog water. This means that the ^{14}C activity of DIC does not reflect the ^{14}C activity of atmosphere, but is ^{14}C -depleted. This results in an artificial aging, the so-called 'hard water effect' inherited by algae cells and which can show wide variation (Fontana, 2005; Macdonald et al., 1991). See Figure 1 on bulk organic matter.

Consequently, algal macrofossils should be avoided if possible. If there is no other choice, an evaluation of the reservoir age should be associated with the measurements. This could be done by the collection, in a 'reference' level, of algae macrofossils and subaerial plants or beetles macrofossils. But once again, attention must be brought to the choice of the reference level and to the beetle species. Indeed, the level chosen to determine the reservoir age should correspond to an equivalent climatic context to the one to which the correction will be done. Likewise, the ecological niche of beetle species has to be known in order to avoid beetles that feed with algae or that burrow.

There are some examples of peat bogs that do not seem to be subjected to the 'hard water effect,' such as the case of lacustrine or palustrine environments developed on glacial till (Blaauw et al., 2004; Walker, 2001). Nevertheless, such occurrences are not common.

Terrestrial Plant Macrofossils

Based on the assumption that superior (terrestrial) plants are less susceptible to contamination by inert carbon than their aquatic counter parts, since they obtain their carbon by subaerial photosynthesis, many scientists have advocated the exclusive use of superior plant macrofossils for radiocarbon-dating lacustrine and palustrine sediment sequences. The development of the AMS radiocarbon-dating technique has facilitated the use of these plant macrofossils as a routine material for dating, as a reasonable analytical precision in radiocarbon measurement

Figure 1 Radiocarbon ages obtained from macrofossil and bulk organic matter samples from Finglas River, southwest Ireland (modified from Turney et al., 2000). Notice the systematic aging of radiocarbon ages obtained on bulk organic material compared to *Salix* leaves and the age difference between *Carex* seeds and *Salix* leaves.

can usually be obtained from as little as 2 mg of organic matter. This amount can typically be extracted from just a few fossil seeds or bracts, or even from a single fossil leaf.

Potamogeton Seeds and Other Floating Superior Plant Macrofossils

Floating superior plants photosynthesize from the CO_2 available at the water surface that mostly results from a mixture of free atmospheric CO_2 and degassing DIC. Indeed, a high content of mineral carbon in water can result from strong limestone catchment erosion or from high organic matter mineralization, such as is commonly observed following a production bloom that may result in DIC degassing. Consequently, floating superior plants inherit part of the DIC ^{12}C : ^{14}C composition and even if diluted, the 'hard water effect' affects the ^{14}C activity of *Potamogeton* seeds. The conversion of this activity into a date would induce significant aging (i.e., the sample appears too old) or rejuvenation (too young) in the case of modern environments with high organic matter mineralization. Indeed, the DIC may thus be imprinted by peak bomb organic carbon and then the floating plants appear ^{14}C -enriched (Olsson and Kaup, 2001).

There are some examples of peat bogs where DIC degassing is not significant, and dating obtained on *Potamogeton* seeds gives a reliable chronological framework (Walker et al., 2001). Nevertheless, since this is linked to water organic production and thus to seasonal cycle, the degassing can fluctuate greatly and therefore, a quantitative evaluation is difficult. It is hazardous to work on this kind of macrofossil. Therefore, it is better to avoid the use of floating plant macrofossils for dating as much as possible.

Sphagnum, Terrestrial Mosses, and Smaller-Sized Superior Plant Macrofossils

As ombotrophic peat deposits are very common and sphagnum-formed, sphagnum macrofossils are often used for ^{14}C dating (Kilian et al., 1995). These superior plants do not grow in the water context and are not subjected to a 'hard water effect' or DIC degassing influence; however, they are not free of aging effects due to the 'hard water effect'! Indeed, palustrine areas may be highly organic, especially in ombotrophic bogs, and then very efficient environments for organic matter mineralization. As this mineralization concerns recent as well as old organic matter, the resulting mineralized CO_2 emitted by the 'soil' shows an old apparent ^{14}C -age. Thus, at the ground surface, CO_2 results in a mixture between free atmospheric CO_2 and mineralized organic matter CO_2 . At a lower scale, this effect can be linked to the well-known canopy effect in a tropical forest. Close to the surface, the smaller-sized superior plants like sphagnum and mosses may thus show ^{14}C aging (Jungner et al., 1995). Some mosses are calciphilous and thus may incorporate limestone as a carbon source, this effect may result in an aging (Zazula et al., 2006). These mosses may not constitute the most reliable support to establish a chronology.

Considering the uncertainty ranges associated with ^{14}C dating, this aging can sometimes not be significant, and chronologies based on ^{14}C on sphagnum can be reliable. But with

the increasing precision of ^{14}C dating, the aging risk linked to organic matter mineralization has to be taken into account.

Larger-Sized Superior Plant Macrofossils

Finally, larger superior plant macrofossils seem to be the most suitable macrofossils for ^{14}C dating. A plethora of such macrofossils can be found in peat and lake sediment. We can list needles of *Pinus*, *Larix*, *Picea*, seeds of *Betula*, *Carex*, *Eleocharis*, leaves of *Salix*, *Dryas*, *Sphagnum*, *Erica*, *Calluna* as the most common (Figure 2).

On account of their high resistance to diagenesis, *Carex* seeds were intensively used in support of chronological frameworks. However, this effective resistance does not permit verification of the state of preservation and then the avoidance of some possibly reworked or redeposited seeds that would be recognized from indices on macrofossil shape and entirety. This was the origin of some inconsistent chronologies based on macrofossils of several centimeter tall superior plants (Turney et al., 2000). We would recommend the collection of 'fragile' macrofossils from which it is easy to check that they are unlikely to have been physically transferred within the sediment matrix and/or otherwise reworked from the surrounding catchment and/or reworked by fauna and/or the rhizosphere. For example, intact *Betula* seeds surrounded by a fragile voile or survival of the fragile *Salix* leaves can be an ideal candidate for ^{14}C dating to establish a chronological framework.

Toward Specific Compounds

The dating of pleniglacial sediments remains problematic due to the very low content of identifiable plant macrofossils. The development of AMS technology now allows ^{14}C measurements on extremely low amounts of carbon (as little as 10 μg , potentially even less) and offers the new prospect of specific-compound dating. In this way, we focus on organism-specific organic compounds called 'biomarkers' or 'specific compounds.' This technique was mainly used in marine environments (from Eglinton et al., 1996) but is more and more common on continental paleoclimatic studies (Hou et al., 2010; Smittenberg et al., 2004; Uchikawa et al., 2008).

Two ways of sample preparation coexist: elimination of all nonselected compounds and extraction of the selected compound from a complex mixture by chromatography. The first one remains time-consuming and fastidious but can easily be done in all laboratories not fully equipped with chromatography whereas the second is more direct but requires to be equipped in preparative gas chromatography (Prep-GC), preparative liquid chromatography (Prep-LC), and/or preparative high pressure liquid chromatography (Prep-HPLC). Chromatographs are either associated with a fraction collector for offline physical measurement (after conversion into CO_2 then graphite) or coupled to a gas source AMS for online measurements.

As has been done for macrorest deposits, the selection of the targeted biomarker has to account for the physiology and the way of life of the organism from which it is extracted. Sillafin (diatom-specific protein) extraction is thus done to establish a chronological framework on paleoclimatic records

Figure 2 Pictures of some common macrofossils. (a) *Carex* seeds, (b) *Betula* seeds, (c) *Salix* leaves (from <http://tchester.org>), (d) *Eleocharis* seed (from <http://geography.berkeley.edu>).

deriving from diatom assemblages or isotopic signatures (Hatté et al., 2008; Ingalls et al., 2004), but this material does not solve the problem of the hard-water effect. Also, *n*-alkanes from the degradation of leaf wax (Collister et al., 1994) may now be sampled and analyzed by Prep-GC (Uchikawa et al., 2008) to establish lacustrine chronology. Only higher plants have wax on their leaves. This would be one way to avoid any hard-water effect linked to algae, but it does not avoid the reworking risk.

Besides chronological issues, specific-compound radiocarbon dating is used to elucidate the effect of different transport mechanisms, particle association, and chemical reactivity between different carbon reservoir and thus to address key issues of modern carbon cycle understanding (Hou et al., 2010; Huang et al., 1999; Mollenhauer et al., 2009; Pearson and Eglinton, 2000). This is done by comparing radiocarbon ages of lignin phenols and co-occurring plant-wax lipids like long-chain *n*-alkanes, *n*-alcohols, and *n*-fatty acids. Likewise, specific-compound radiocarbon dating allows detection of potential fossil-fuel-derived contamination (Lichtfouse et al., 1995).

Reminders and Suggestions

Storage and Macrofossils Preparation

The core storage and the preparation and identification of small macrofossil samples are usually carried out in a nonsterile environment. Wohlfarth et al. (1998) has shown that the long-term storage of wet macrofossil samples appears to have a significant effect on the radiocarbon age obtained, even when the samples are kept cool. Fungal spores and microorganisms

may easily be incorporated into the sample and can easily contaminate the sample if stored cool and wet for several months. Indeed, fungal metabolism takes up CO_2 from the fossil leaf material but also includes carbon from contaminating nutrients in the ambient water during growth. Wohlfarth et al. (1998) observe that even when stored in slightly acidic water (pH 2) and under cool and dark conditions, *Paecilomyces farinosus* may easily grow and absorb CO_2 from the remaining air in the glass bottle and from the ambient water. This recent carbon, when added to the sample, may account for the large errors of several hundred to several thousand years encountered in dating series. They refer to radiocarbon ages that are $\sim 400\text{--}700$ ^{14}C years too young in samples of around 12000 ^{14}C years BP, depending on whether the macrofossils were dried at 50°C or whether they were stored for 2 years at room temperature in deionized water. Earlier investigations on bulk sediments from marine and lacustrine cores, which had been stored for many years at a temperature of 4°C , also showed unreliable radiocarbon dates due to contamination by recent carbon from modern, terrestrial bacteria (Colman et al., 1996; Geyh et al., 1974). Similar studies designed to constrain the impact of storage and chemical treatment on isotopic composition reveal that inadequate storage conditions might result in a 2‰ $\delta^{13}\text{C}$ distortion on low organic carbon sediment (Gauthier and Hatté, 2008).

Small Samples

Even though the AMS dating method can provide results with acceptable accuracy from small amounts of carbon, a minimum amount of material is still required. If the samples are too small, they may yield very little datable carbon after

pretreatment and can be more easily biased by contaminants, in addition to having larger standard deviations. Processing sample under continuous flow of inert gas (He or N₂) can be considered as an alternative to the common vacuum lines. Working under gas pressure decreases the risk of modern carbon contamination by incorporation of atmospheric CO₂. This method does not require so many changes in the technological suite. Likewise, but harder to implement and to process, chemical treatments on fragile samples might be treated in a gloves box with a clean neutral gas atmosphere.

Chemical Pretreatments

The most common chemical pretreatment used for plant macrofossils consists of three steps, as follows:

1. acid leaching to remove any carbonate and any 'fulvic' acids,
2. alkali treatment to remove 'humic' acids, and
3. acid rinsing to remove modern carbon potentially precipitated during the alkali step.

A cellulose extraction can be performed on large wood samples (Leavitt and Danzer, 1993). Sometimes, but fortunately rarely, contaminants can be incorporated during the chemical pretreatment.

The alkali step may induce atmospheric carbon incorporation into the organic structure or adsorption of volatile organic molecules on cell walls that cannot always be removed by the classical method using a subsequent acid step (Hatté et al., 2001; Kilian et al., 2002). Some laboratory solutions have been proposed that are based on an additional oxidation step (Bird et al., 1999; Hatté et al., 2001) to discard most of the modern carbon incorporated during the alkali step. An alternative would be to perform the chemical pretreatments under an inert atmosphere. However, no chemical pretreatment can correct for fungal and microbial contamination linked to the core and macrofossil storage.

Conclusion

The aim of this article was to give a general view of plant macrofossils founded in Quaternary sediments or archaeological settlements and to discuss their suitability and reliability for ¹⁴C-AMS dating.

Three conclusions can be made:

- Long-term and cool storage of cores and wet macrofossil samples prior to the radiocarbon measurement has significant consequences on the radiocarbon age obtained.
- A chronology based on a type of macrofossil appearing as coherent in one specific environment does not necessarily mean that this macrofossil is the most reliable support for ¹⁴C dating. Nothing is universal!!
- A good choice of a macrofossil for ¹⁴C dating several 10 years ago does not mean that it is still the best choice today. Increasing precision of ¹⁴C dating means that a serious consideration of the meaning of the choice of macrofossil and its relationship with the event to be characterized must be made.

Briefly, ¹⁴C on well-chosen plant macrofossils constitutes a powerful tool to establish chronological frameworks in terrestrial environments.

Introduction

Understanding relative sea-level changes helps explain critical interactions in Earth environmental systems throughout the Quaternary. Relative sea-level changes record transfers of mass between oceans and continents during expansion and contraction of great ice sheets driven by climate change. They record extreme events, including storm surges and tsunamis, as well as predictable daily tides. They also record vertical movements in the Earth's crust over a wide range of timescales, from coseismic uplift and subsidence during great, $M_w > 8$, plate-boundary earthquakes, through century- and millennial-scale movements driven by the process of glacial isostatic adjustment (GIA), to timescales beyond the Quaternary, as global ocean volumes change as a result of plate-tectonic movements. Vertical changes

in relative sea level result in major horizontal shifts in coastal environments. The combination of all these factors means that no single location on Earth records all of these changes. No location can be considered stable and therefore a record of 'absolute' sea-level change over different time-scales. Perhaps the most significant advance in studies of Quaternary sea-level change is the recognition that key questions will only be answered by the integration of multiproxy-based reconstructions of sea level with model predictions.

For the timescale of the whole Quaternary this can be simply illustrated by the example of oxygen isotope records from ocean sediments used to reconstruct global eustatic sea-level change through the Quaternary. Oxygen isotope variations, $\delta^{18}\text{O}$, in Foraminifera preserved in deep ocean sediments are a commonly cited proxy for developing continuous reconstructions

of ice volume and sea level over late Quaternary time and earlier. But direct conversion of $\delta^{18}\text{O}$ changes into ice volume and sea level has two critical problems (Clark and Mix, 2002; Duplessy et al., 2002; Lea et al., 2002). First, $\delta^{18}\text{O}$ in fossil oceanic Foraminifera is a function of both the isotopic composition and the temperature of the water in which the Foraminifera grew. Second, $\delta^{18}\text{O}$ of ocean water is a function of both mean ocean $\delta^{18}\text{O}$, itself reflecting continental ice volume and the average $\delta^{18}\text{O}$ of continental ice, and local hydrological effects. Thus, we require information on ice volumes on each of the major ice sheets and their different isotopic compositions (Duplessy et al., 2002) as well as temperature and salinity changes of the water in which the Foraminifera grew. In summary, graphs that show $\delta^{18}\text{O}$ changes in oceanic Foraminifera through multiple glacial cycles, together with a second axis labeled meters sea-level change are not direct observations of the latter but estimates, or reconstructions, from models based on a long series of assumptions and calculations, some of which are not well constrained.

General Principles

Along with many aspects of Quaternary Science, research into sea-level changes advanced significantly with the development of improved methods for dating sediment, especially radiocarbon dating. Perhaps, equally significant were the activities of international groups of scientists under the auspices of International Geological Correlation Programme (IGCP) and INQUA. From the 1970s onward, through a series of IGCP Projects and INQUA Commissions and Subcommissions, national, regional, and international sea-level research benefited from high-profile, interdisciplinary conferences, and field meetings that brought forward many new ideas, researchers, and research topics that ranged in spatial scale from local to global. Early debates noted the regionally different patterns of emerged and submerged shorelines and sediments. Glacio-isostasy was an early hypothesis and part explanation, but the significance of hydro-isostasy and the effects of gravitational attraction on the ocean surface only became accepted with advances in geophysical models and their comparison with reconstructions. Early model-sea-level reconstruction comparisons suffered from highly variable quality control on reconstructions of relative sea level and their incorporation into databases. Methodological debates and international initiatives under IGCP and INQUA brought an improved degree of rigor in data collection and interpretation during the 1980s (Devoy, 1987, chapters 1 and 7; van de Plasche, 1986). These are summarized further in following sections.

From the 1960s onward, the literature contains a recurring debate on the general pattern of eustatic sea-level change since the Last Glacial Maximum; was it a generally smooth function with time or characterized by a series of submillennial oscillations of decimeter to meter scale superimposed on the broader scale pattern of change? To what extent are these climatically induced changes or noise in the sedimentary record, uncertainties in the age and elevation estimates of paleosea-level indicators? Despite better age controls and improved sampling techniques, these complexities continue to confound interpretations. Much of the difference of opinion may be resolved by a more explicit consideration of scales, both spatial and temporal, within a hypothesis testing framework. Not all studies address these issues explicitly, with the danger that

factors important at one scale may not be adequately resolved for a study of processes assumed dominant at another scale. For example, when studying the spatial pattern of isostatic deformation of the crust, it is inherently assumed that local factors that control each sea-level index point used have been quantified, taken into account, or removed from subsequent analyses.

For each geographical location (φ) the change in relative sea level (ΔRSL) at time t , where t is the time relative to present (Shennan et al., 2012):

$$\Delta\text{RSL}(\varphi, t) = \Delta\text{EUS}(t) + \Delta\text{ISO}(\varphi, t) + \Delta\text{TTECT}(\varphi, t) + \Delta\text{LOCAL}(\varphi, t) + \Delta\text{UNSP}(\varphi, t) \quad [1]$$

where:

- $\Delta\text{EUS}(t)$ is the time-dependent eustatic sea level, derived from the model of ice history, that would result by distributing any meltwater evenly across a rigid, nonrotating planet and neglecting self-gravitation in the surface load.
- $\Delta\text{ISO}(\varphi, t)$ is the total isostatic effect of the glacial rebound process including the ice load (glacio-isostatic), water load (hydro-isostatic) and rotational contributions to the redistribution of ocean mass.
- $\Delta\text{TTECT}(\varphi, t)$ is the tectonic effect, which can operate at different timescales.
- $\Delta\text{LOCAL}(\varphi, t)$ is the total effect of local processes within the coastal system. Since we use observations from the sedimentary record to reconstruct relative sea-level elevation we can express these as the sum of $\Delta\text{TIDE}(\varphi, t) + \Delta\text{SED}(\varphi, t)$, where $\Delta\text{TIDE}(\varphi, t)$ is the total effect of tidal regime changes and the elevation of the sediment with reference to tide levels at the time of deposition (e.g., Shennan and Horton, 2002; Uehara et al., 2006). $\Delta\text{SED}(\varphi, t)$ is the total effect of sediment consolidation since the time of deposition. Numerous studies show that this can be both a major process in coastal evolution (Horton and Shennan, 2009; Tornqvist et al., 2008; van Asselen, 2010) and a key variable in reconstructing relative sea-level change from index points taken from sediments.
- $\Delta\text{UNSP}(\varphi, t)$ is the sum of other unspecified factors, either not quantified or not thought of. Implicitly most studies assume their total effect close to zero and random.

When we plot reconstructions of relative sea-level change using geological sea-level index points and find a scatter of data points that do not overlap, this indicates one or more of the following: (1) underestimation of age and/or elevation error terms; (2) plotting data from a too large spatial extent, so incorporating differential GIA; (3) underestimation of $\Delta\text{LOCAL}(\varphi, t)$; (4) evidence of $\Delta\text{UNSP}(\varphi, t)$ (Shennan et al., 2012).

Depending upon the hypothesis of the study in question, one or more of the factors on the right-hand side of eqn [1] are assumed constant, known, or negligible, depending upon the temporal or spatial scale appropriate. If these are not considered, then the study is in danger of becoming just a description of proxy data observed in the field or laboratory. As demonstrated in other disciplines such as geomorphology, as the time span considered becomes smaller, then the spatial scale of dependent variables to be considered also decreases. Figure 1 illustrates global to local scale processes that contribute to sea-level change (Shennan et al., 2012).

For timescales in the order of 10^2 – 10^5 years, we would mostly consider those relationships in blue (Figure 1), for

Figure 1 Schematic diagram of global to local scale processes that contribute to sea-level change. Note that it does not include Earth rotation. For timescales in the order of 10^2 – 10^5 years we would mostly consider those relationships in blue; for timescales $\sim 10^0$ – 10^2 years, and the local scale of individual coastal environments we must also consider those in black; and for long timescales, $>10^5$ years, those relationships in red.

example, when comparing geological indicators of sea level with GIA model estimates of sea level. At shorter time periods, 10^0 – 10^2 years, and the local scale of individual coastal environments we must also consider those in black. Factors at these scales could dominate the elevation at which sea-level index points form, yet we may be tempted to assume that they can be accounted for when such indicators are used to reconstruct sea level in the past.

At long timescales, we must also consider those relationships in red. This includes the influence of sediment erosion and deposition on the ocean geoid and solid earth. Across Quaternary timescales, global sediment transfer from the continents to oceans since the mid-Pliocene are of the same order of magnitude as the glacial–interglacial transfer of ice and meltwater, so the effects of sediment unloading and loading on ocean bathymetry and the ocean geoid deserve investigation alongside climate change and GIA (Shennan, 2011).

Note how a factor such as plate tectonics can be considered over different timescales: driving changes in ocean shape, sometimes called tectono-eustasy; crustal deformation adjacent to plate boundaries so influencing Holocene-scale relative sea-level change at sites such as Barbados and Huon Peninsula; and abrupt changes during great earthquakes, with coseismic land movements, displacement of the sea floor and tsunami generation.

Sea-Level Index Points and Reconstructions of Relative Sea Level

IGCP Projects 61 and 200 (van de Plassche, 1986) promoted a universally applicable approach to the reconstruction of relative sea-level histories for different locations and environments. Reliable reconstructions of past changes in sea level relative to present, with quantified uncertainty terms, come from *in situ* sediments and morphological features whose origin was controlled by paleosea level. Where such sediments and morphological features survive they can be used as sea-level index points by defining four attributes: location, age, altitude, and tendency. Although this formal approach and terminology never attained universal application, the principles behind them can be seen in all reconstructions of paleo-sea levels, as evidenced in the separate entries in the sea-level section.

Location Attribute of a Sea-Level Index Point

Once it is established that the sediment or morphological feature has not been transported from its original location, this attribute consists simply of its geographical coordinates.

Age Attribute of a Sea-Level Index Point

The majority of reconstructions used for studies of sea-level changes since the Last Glacial Maximum have their ages measured by radiocarbon techniques and most modern studies use calibrated ages expressed with 95% confidence limits. Other widely used methods for establishing a chronology include various measurements based on sediment characteristics, such as luminescence, isotopic properties, and archaeological evidence. Morphological expressions of past sea level, including beaches, notches, cliffs have the great advantage that they provide a spatial expression of the consistency or variation in relative sea level, but their use is severely limited if they cannot be dated reliably. Organic material incorporated in raised shorelines, for example, is not always *in situ*, so provides only a limiting age of the feature. The most reliable sea-level index points should have at least one type of corroborating evidence to support the radiocarbon age and to demonstrate continuity of sedimentation or formation.

Elevation Attribute of a Sea-Level Index Point

Few sea-level index points formed exactly at paleomean sea level. Many represent environments within the upper part of the tidal range but in total they cover the full tidal range, the shallow subtidal zone and, for limiting dates, beyond. Limiting dates come from either samples from freshwater environments inland of the paleocoastline and at or above the past high-tide level or fully marine environments for which only a minimum water depth can be given. In reconstructing relative sea-level change, the dated freshwater sample must lie, on a plot of elevation against age, at or above data points such as those sea-level index points whose origin was directly controlled by the paleosea level. The same argument applies to dated samples that represent marine environments. They must lie at or below the other index points on the altitude versus age plot.

'Indicative meaning' defines the relationship of the sample to tidal range and allows us to measure relative sea-level change, defined relative to present (van de Plassche, 1986). Indicative meaning comprises two parameters, a reference water level (e.g., mean high water of spring tides – MHWST; or a tide level with an offset, called the indicative difference, e.g., MHWST +0.2 m) and indicative range (the vertical range over which the dated indicator could occur as it is forming). The reference water level allows calculation of sea-level change relative to present, based on the elevation of both the index point and the reference water level to a common datum. This may be the national datum or one defined locally through a series of observations of present-day tide levels. Most analyses assume no change in tidal range since the time of deposition but various modeling studies show this may be an important factor, with changes up to a few meters depending on the amplification of the tidal wave as the coastline shape and bathymetry change through time (Gehrels et al., 1995; Shennan and Horton, 2002; Uehara et al., 2006). Other factors that contribute to the height uncertainty or error term come from all of the measurements that must be made during the sampling process.

The total height uncertainty or error term, e_h is calculated by:

$$e_h = \sqrt{(e_1^2 + e_2^2 + \dots + e_n^2)}$$

where $e_1 \dots e_n$ are the separate sources of uncertainty, expressed as 95% confidence limits.

A final factor with a potentially significant effect is sediment consolidation. There is no widely accepted approach to quantifying this, not least because the necessary physical parameters of the sediments most probably have not been measured. Some studies include an empirical correction for sediment consolidation while others aim to minimize the problem by concentrating on sea-level index points underlain by sediments that undergo minimal or no consolidation. In paleoestuarine sequences, these index points usually come from thin organic tidal marsh sediment or peat that overlies glacial till or other pre-Holocene sediments. Much of the scatter of index points in relative sea-level graphs from estuaries with thick Holocene sequences derives from the net effect of sediment consolidation, where the index points from the basal tidal marsh sediment or peat mostly lie within the upper part of the scatter (Shennan and Horton, 2002). Residuals from the general trend show statistically significant correlations with various sediment characteristics related to consolidation. In general, for paleoestuarine environments best-fit relative sea-level reconstructions or predictions would lie toward the top of the scatter.

Tendency Attribute of a Sea-Level Index Point

The tendency of a sea-level index point describes the increase (positive sea-level tendency) or decrease (negative sea-level tendency) in marine influence recorded by the index point. Most analyses of the pattern of sea-level tendencies consider changes at the local scale, either within or between estuaries, such as relationships between horizontal shifts in the coastal sedimentary environments, sediment accumulation, consolidation and the potential driving mechanism of relatively small, ~decimeters, vertical changes in sea level (Allen, 1997). In the analysis of larger-scale processes, such as testing relative sea-level predictions from isostatic adjustment models, observations of a change in sign of the tendency are useful in determining the turning points in relative sea-level curves, whether from the near-field or far-field. Furthermore, sea-level tendencies show whether relative sea level was slightly above or below present in the last few thousand years, thus identifying the geographic limits of the transition from mid-Holocene relative land uplift to relative submergence.

Sea-Level Changes: Local to Global

Each of the contributions to the Quaternary sea levels section summarizes the range of different processes that control registration of changes in sea level in different locations. Implicitly or explicitly in different degrees, they address the issues of scale, age, location, tendency, elevation, and the associated errors. They reflect the great diversity of issues that studies of Quaternary sea-level change contribute to:

- global ice volumes and meltwater discharge since the Last Glacial Maximum;
- regional patterns of isostatic uplift;

- coseismic and interseismic deformation of the crust close to plate boundaries;
- late Holocene trends as a background to global warming;
- centimeter scale changes caused by short-term climate, oceanographic, or hydrological changes.

To illustrate the inter-relationships within these studies, we can look at the progress in integrating quantitative geophysical models, global meltwater discharge (eustatic sea-level change), and local reconstructions of relative sea-level change around the world. As noted above, perturbations to the ocean geoid and deformation of the solid Earth in response to climate-induced ice and ocean water mass redistribution mean that no single location records only the eustatic component. Far-field locations, those distant from the late Quaternary ice sheets, most closely resemble the eustatic component but they still record relative sea-level change. Indeed, attempts to fit relative sea-level reconstructions from far-field locations with numerical models of GIA and models of global ice distributions reveal significant misfits (Bassett et al., 2005; Lambeck et al., 2002; Milne et al., 2002; Peltier, 1998, 2002a,b). These differences arise from the number of unknown parameters, including Earth model parameters, ice model parameters, as well as uncertainties in relative sea-level reconstructions. While GIA models successfully explain the major differences in relative sea-level changes on a global scale, frequently summarized by figures of six characteristic zones it is infrequently recognized that existence of the zones and the position of the boundaries between them are a function of both the Earth and deglaciation models adopted.

Most approaches use an Earth model that is a spherically symmetric, self-gravitating, compressible Maxwell viscoelastic body. Differences exist between models in how to treat the viscous structure from the surface to the core-mantle boundary. Lambeck et al. (1996) compared three-, four-, and five-layer models and while their optimum solution is for a five-layer model, a three-layer model gives similar results and is adequate for predicting relative sea-level change. In contrast, Peltier (1998, 2004) models the depth-dependence of mantle viscosity in much smaller steps, each ~50–70-km depth, but the major changes occur at the base of the model lithosphere and ~670-km depth. In a three-layer model, the upper layer, to simulate the lithosphere, has a large viscosity so that it behaves as an elastic plate on late Quaternary timescales. The second layer, a model for the upper mantle, extends from the base of the model lithosphere to the 670-km deep seismic velocity discontinuity, below which, the core-mantle boundary simulates the lower mantle.

Differences in model parameters were much greater in analyses during the 1990s, well illustrated by the value used for the depth to the base of the lithosphere, ranging from the ‘thin lithosphere’ models, ~30 km to ‘thick lithosphere’ models, ~200 km. With subsequent analyses using relative sea-level data from more locations, with greater reliability as a result of using the approaches discussed above, and other types of data, including the gravity field, perturbations in Earth rotation and measurements of present rates of crustal motion, differences in model parameters are now less. For example, most models use a lithosphere in the range ~65–95 km, except for modeling areas close to plate boundaries for which a spherically symmetric Earth model is not applicable.

In order to test Earth model parameters, we require relative sea-level data from a range of areas because of the different sensitivities to mass redistributions of ice and water. The glacial isostatic component of predicted relative sea-level change for regions formerly beneath large ice sheets at the Last Glacial Maximum, such as Scandinavia and North America, show a pronounced sensitivity to deeper Earth structure, especially lower mantle viscosity. In contrast, predictions of relative sea-level change for regions beneath or close to smaller ice sheets, such as the British Isles, are highly sensitive to shallow Earth structure, especially lithospheric thickness and the viscosity of the upper mantle. Data from far-field locations help constrain upper and lower mantle parameters but are relatively insensitive to different models for the lithosphere.

Despite more than 150 years of research, estimates of ice sheet dimensions, from local to global scales, at different times during the Quaternary remain contentious. The CLIMAP study of the Earth at the Last Glacial Maximum (CLIMAP, 1981) presented two reconstructions: a ‘minimum model’ with 127 m of ice-equivalent sea-level lowering, or eustatic change; and a ‘maximum model’ with 163 m of eustatic change. More recent assessments narrow the uncertainty of eustatic sea level at the Last Glacial Maximum to a range from ~114 to 135 m (Clark and Mix, 2002; Lambeck et al., 2002; Milne et al., 2002; Peltier, 2002b). The isostatic effects, $\Delta\text{ISO}(\varphi, t)$ in eqn [1], and any tectonic movement, $\Delta\text{TECT}(\varphi, t)$, mean that no site, even in the far-field, exactly records eustatic sea-level change, only relative sea-level change at the site, $\Delta\text{RSL}(\varphi, t)$. As a result, models of eustatic sea-level change, expressed as ice-equivalent sea level, differ as a result of their calibration against different datasets of relative sea-level reconstructions and the Earth models used to predict relative sea-level change. For example, the differences between the ICE-4G and ICE-5G (Figure 2) result primarily from new data becoming available from Bonaparte Gulf and Sunda Shelf together with various lines of evidence that pointed to a larger, multidomed Laurentide ice sheet (Peltier, 2004).

The main far-field records (Figure 3) come from Barbados (Bard et al., 1990; Fairbanks, 1989), Tahiti (Bard et al., 1996), Huon (Chappell and Polach, 1991; Cutler et al., 2003), Bonaparte Gulf (Lambeck et al., 2002; Yokoyama et al., 2000) and Sunda Shelf (Hanebuth et al., 2000). The data from Barbados, Tahiti, and Huon require a correction for long-term tectonic movement, usually corrected assuming a uniform tectonic uplift of 0.25, –0.1, and 1.76 mm year^{–1}, respectively.

A further, highly significant complication in reconciling the far-field relative sea-level records with global ice sheet reconstructions is the high dependence upon where it is assumed the ice was at each point in time, since this influences the effect of gravitational attraction on the water in the ocean. When each ice sheet melted remains contentious and this can be illustrated with the debate on the existence of major changes in the rate of global meltwater discharge, especially the so-called meltwater pulses: MWP1a ~14.0 ka BP and MWP1b ~11.3 ka BP.

The existence, or not, of meltwater pulses and their magnitude has considerable implications for understanding rapid climate change and numerous feedback mechanisms in the climate–ocean–Earth system. Differences remain in the

Figure 2 Four recent models of global ice melt since the Last Glacial Maximum shown as ice-equivalent sea-level, or eustatic sea-level change (Bassett et al., 2005; Fleming et al., 1998; Peltier, 1998, 2004). Differences arise from different interpretations of the data used to delimit relative sea levels at the Last Glacial Maximum and different Earth and ice model parameters used to explain relative sea-level changes at sites (see Figure 3).

Figure 3 Observed sea-level index points and sea-level predictions at five far-field locations (data from Bassett et al., 2005). Predictions differ on the basis of the assumed contribution to meltwater pulse 1a from the Antarctic ice sheet (in units of equivalent eustatic sea-level change). Dashed line is for no contribution from the Antarctic ice sheet; solid line for a dominant contribution from the Antarctic ice sheet, 15 m out of 24 m equivalent eustatic sea-level rise. Sunda II shows the subset of cores from the northerly sites, sufficiently far away from the other Sunda sites to give different relative sea-level predictions.

interpretation of field observations, with the evidence for MWP-1a generally more accepted than MWP-1b (Bard et al., 1996; Fairbanks, 1989, 1990). Most eustatic models include a distinct MWP-1a but others argue for a nearly uniform rise for the whole of the period ~15–7 ka BP (Figure 2). At Barbados,

Fairbanks (1989) recorded MWP-1a as ~24 m relative sea-level rise in less than 1000 years. The geographical source of the meltwater in MWP-1a impacts upon both the spatially variable relative sea-level change recorded at far-field and near-field sites and our understanding of climate change and the

processes leading to rapid deglaciation. Peltier (2005) argues for a Northern Hemisphere source, primarily but not exclusively, Laurentide, whereas others suggest a significant Antarctic contribution (Bassett et al., 2005; Clark et al., 2002). Figures 2 and 3 demonstrate the significance of these contrasting views in relation to relative sea level at the key far-field locations.

Using the same model of eustatic sea-level change (Figure 2) and an Earth model tuned to fit the Barbados reconstructions of relative sea level, Bassett et al. (2005) show there are significant differences in the predictions of relative sea-level change for the other far-field locations (Figure 3), depending upon whether the dominant contribution for MWP-1a was from Antarctica or not. The dashed line is for no contribution from the Antarctic ice sheet and the solid line for a dominant contribution from the Antarctic ice sheet, 15 m out of 24 m equivalent eustatic sea-level rise. Peltier (2004) offers a different analysis, based on different Earth and ice models, that shows almost the opposite, a predominant Laurentide source for MWP-1a. Peltier (2004) also draws attention to the broad error terms in the far-field data that define MWP-1a, showing that any amplitude in the range of 10–25 m would appear to be allowed. This highlights the more general difficulty of identifying changes in the rate of sea-level change given the error terms of most index points. Nevertheless, it is possible to test explicitly such an hypothesis, for example, the magnitude of MWP-1a, by seeking its signal in a near-field location where the rate of glacio-isostatic uplift is of similar magnitude but of opposite sign.

Figure 4 shows relative sea-level changes at Arisaig, northwest Scotland, since ~16 000 cal years BP (Shennan et al., 2005). The marine limit occurs between ~34 and 38 m above present. Rapid relative sea-level fall continues until at least ~14 500 cal years BP. This fall constrains the acceleration in global meltwater discharge around 14 000 cal years BP, MWP-1a. If meltwater discharge exceeded the rate of relative sea-level fall then sediment

sequences around 15 m above present (Figure 4) would record a change in sea-level tendency, from negative to positive then back to negative. No reversal in relative sea level occurs in any of the sites around this elevation although it remains possible that a reversal falls within the gap of data 13 000–14 000 cal years BP. Negative sea-level tendency for all sea-level reconstructions from ~16 000 to ~12 000 cal years BP limit the acceleration of eustatic sea-level rise during meltwater pulse 1a to ~30 mm year⁻¹ or ~11 km³ year⁻¹ meltwater discharge. This is approximately half the rate predicted by Fairbanks (1989, 1990).

One other continuing debate is the nature of late Holocene deglaciation. The majority of opinion up to the 1980s was that all significant ice melt ceased abruptly at ~7 ka BP. Since then a number of analyses show a gradual end to melting with up to 3 m equivalent sea-level rise since ~7 ka BP, with some debate on when melting ceased, by 4 ka or continuing to preindustrial times (Fleming et al., 1998; Lambeck et al., 1998, 2002; Nakada and Lambeck, 1988; Peltier, 1998, 2004; Peltier et al., 2002; Shennan et al., 2002). The rapid termination of ice melting shown in Figure 3 reflects the poor constraint provided by the long time-series far-field data. Numerous studies show that this produces a Holocene highstand around 6000 BP that is too sharply defined compared to reconstructions at other far-field and near-field sites (Fleming et al., 1998). The predicted relative sea-level curve in Figure 4 shows a flattened peak to the mid-Holocene highstand and numerous sea-level index points from the field area indicate that the highstand persisted more than 1000 years before the onset of any measurable relative fall in sea level (Shennan et al., 2005). These point to gradual cessation of melting of the Laurentide and Antarctic ice sheets rather than an abrupt termination. The model used in Figure 4 has melting ending at 2000 BP and also gives predictions consistent with reconstructions of mid-Holocene relative sea-level above present on Pacific Islands (Peltier et al., 2002; Shennan et al., 2002).

Figure 4 Reconstructions and model predictions of relative sea-level change 18 000 cal years BP to present at Arisaig, northwest Scotland (Shennan et al., 2005). Age error bars for sea-level index points indicate the maximum and minimum calibrated ages; the vertical bar crosses at the median calibrated age and shows the sum of all quantified or estimated elevation errors. Relative sea level must lie at or below limiting dates, shown as solid symbols ■. Model predictions come from the modified version of Peltier et al. (2002), described as model 3 in Shennan et al. (2002).

Geomorphological Indicators

Introduction

At any time, marine and coastal processes produce many kinds of geomorphologic marks, especially on rocky shores, that are related to the contemporary sea-level position. After a rise in the relative sea level, marks that became submerged are generally eroded or fossilized when capped by sediments. In the case of a fall in the relative sea level, marine marks are rapidly eroded if they remain in the reach of wave action in the mid-littoral zone. Above in the supralittoral zone, which is never submerged but may be kept wet by spray, erosion is limited to microholes produced by lichens or Cyanobacteria. At higher elevations, the marine or maritime action becomes negligible and geomorphologic marks are exposed only to the slow action of weathering and diagenesis processes. A good knowledge of the marine features related to the present sea level is essential to identify and interpret marks related to former sea levels (Pirazzoli, 1996, 2005).

Erosion Marks

Erosion features which may be useful as sea-level indicators can be preserved only in hard rock and occur in a vertical range that depends mainly on site exposure.

Notches (Tidal, Abrasion, and Structural)

A marine notch is an indentation or undercutting, a few centimeters to several meters deep, left by sea erosion in coastal rocks. In coastal regions affected by rapid vertical movements, incipient notches may form sequences of stepped erosional shorelines, like the nine ‘ripple notches’ developed between 4 and 1.7 ka BP in Antikythira Island (Greece; Pirazzoli, 1986, photo 16), or the spectacular ‘staircase’ of 185 successive raised shorelines built from 8.3 sidereal ka BP to the present, during the emergence of the land due to glacio-isostatic uplift on the eastern coast of Hudson Bay (Canada), reported by Fairbridge and Hillaire-Marcel (1977).

Pirazzoli (1986) has classified several kinds of erosion notches. Tidal notches are one of the most precise sea-level indicators. They are typical mid-littoral erosion features, especially in limestone coasts. In a sheltered site with a moderate tidal range, the most common profiles are recumbent V-shaped or U-shaped forms (Figure 1(a) and 1(a’)), with a vertex located near mean sea level (m.s.l.), the base of the notch near the lowest tide level and the top near the highest tide level. If sea level does not change, the undercut will deepen (Figure 1(b)) and undermine the cliff until the roof collapses. After removal of the fallen material by waves, the base of the former notch will look like a small bench, while a new notch will start forming inside the cliff.

Though early studies ascribed this zonal erosion to solution phenomena, it is now recognized that tidal notch development is mainly related to bioerosion (Torunski, 1979; Trudgill, 1976) and zones of rapid tidal notch development correlate well with zones of major eroding organisms, the maximum density of grazing organisms being in the range of the neap tide (semidiurnal tide of small range which occurs near the time of the first and last lunar quarters, between spring tides) or near m.s.l. Rates of undercutting of $0.2\text{--}5.0\text{ mm year}^{-1}$ have been reported in the literature, the most frequent values being in the order of $1.0\text{--}1.5\text{ mm year}^{-1}$ in the tropics and of 1 mm year^{-1} in the Mediterranean (Laborel et al., 1999).

In areas sheltered from wave action, elevated or submerged tidal notches can be used to specify former sea-level positions with up to a decimeter confidence and also to provide qualitative information on the rate of sea-level change and on tectonic movements. A rapid change in the relative sea level, greater than the tidal range (Figure 1(c)), will uplift or submerge the whole notch, preserving it from further mid-littoral erosion, and a new notch will develop in the new intertidal zone. If the rapid vertical displacement is less than the tidal range, or if the movement is slow and gradual, the floor/roof of the notch will be eroded and the height of the notch will increase (Figure 1(e)). Repeated rapid movements will produce successive overlapping indentations, the so-called ripple notches (Figures 1(d) and 2).

When taken away from mid-littoral erosion, tidal notches may be preserved for a long time and late Holocene features (Figure 3) may be hard to distinguish from last Interglacial ones (Figure 4). In Sumba Island (Indonesia), a tidal notch at 350 m in altitude, of an estimated age of 730 ka, is still clearly visible (Pirazzoli et al., 1993; Figure 3).

Where mechanical action such as abrasion by wave-borne sand or gravel predominates, notches cut in hard rock have a rounded and polished appearance. Such abrasion notches may develop at any level reached by waves or by hydrodynamic agents acting in combination with granular deposits. As wave energy lessens in shallow water, abrasion notches are mainly found in the upper part of the mid-littoral zone, often at cliff base. The vertical precision of abrasion notches as sea-level indicator is generally weak (± 1 to several meters), depending on the local tide and site exposure.

In rock formations consisting of horizontal or gently inclined beds, differential erosion may excavate the weakest layers, along with joints and fissures and thus produce linear reentrants with notch-like profiles. Such features are therefore of a structural origin, that is usually easy to recognize in the field: the attitude does not remain horizontal but follows the original line of weakness, the notch profile may vary along its length, the height of the notch corresponds to certain layers in the rock. Structural notches should be recognized as such and not used as sea-level indicators.

Figure 1 Tidal notch profiles resulting from different compilations of relative sea-level change in sheltered places. The maximum erosion rate is assumed to be 1.0 mm year^{-1} and to occur at m.s.l. Reproduced from Pirazzoli PA (1986) *Marine notches*. In: Van de Plassche O (ed.) *Sea-Level Research: A Manual for the Collection and Evaluation of Data*, pp. 361–400. Norwich: Geo Books.

Figure 2 Marks left by uplifted tidal notches on the limestone cliffs near cape Ladiko, Rhodes Island, Greece. The uppermost notch, at about $+3.7 \text{ m}$ in elevation, developed with a stable relative sea level until ca. $4.9 \text{ }^{14}\text{C ka BP}$, when it was uplifted almost 2 m coseismically. A sequence of six up-and-down coseismic vertical displacements followed, leaving a well-recognizable series of ripple notches (Pirazzoli et al., 1989). Local tidal range is usually less than 0.2 m (photo 4550, May 1978).

Erosion Benches, Platforms, and Strand Flats

When the rock is easily eroded or the slope of a cliff is too gentle to allow an undercut to develop, marine erosion tends to excavate a bench, which, increasing in size, may later become an erosion platform.

The formation of coastal benches and platforms is usually ascribed to the removal by waves of the weathered part of cliffs.

Figure 3 The tidal notch, developed all around a limestone block, has transformed the block into a mushroom rock. South coast of Okinawa Island (Japan), between Mabuni and Gushikami. The retreat point of the notch is at about 2.5 m above present m.s.l. (local spring tidal range: 1.7 m). This 2.5 m uplift is ascribed to a single coseismic vertical displacement dated about $2.35 \text{ }^{14}\text{C ka BP}$ (Kawana and Pirazzoli, 1985; photo 6610, March 1981).

Figure 4 This tidal notch, developed around a middle Pleistocene coral limestone block, projecting from the uplifted surface of the last Interglacial terrace (MIS 5e, minimum age), was formed during the last Interglacial on the northwest coast of Barbados (Schellmann and Radtke, 2004; photo G853, October 2002).

The lowest level of possible weathering probably corresponds to that of constant immersion in seawater, usually in the intertidal zone. Wave abrasion is effective in most rock formations and may occur at any elevation between the highest levels reached by storm waves and the maximum depth at which sediments can be moved by waves. Most often, when a cliff is retreating, it leaves an erosion platform sloping gently seaward in the intertidal zone. The average elevation of shore platforms usually increases with rock hardness. Certain platforms may also develop above high tide level when water supplied by waves can stagnate behind an outer rampart. In high latitudes, strand flats (Klemsdal, 2005) are low shore platforms where disintegrated rock material, resulting from freeze–thaw alternations, has been washed away by waves.

Figure 5 The Kawamine Terrace, developed at about 70–80 m in altitude in the southwestern part of Kikai Island (Ryukyus, Japan), is an erosion surface cut into middle Pleistocene units during an undated high interstadial later than isotope stages 5a (stage 3?; Ota and Omura, 1992). Below, raised Holocene coral-reef terraces (capped by vegetation and villages) can be seen (photo 2221, November 1974).

The accuracy in the reconstruction of past sea-level positions from elevated or submerged benches and platforms will therefore increase when the tidal range is small and will be improved for solid calcareous rocks liable to be attacked not only by physical and chemical processes, but also by bioerosion. In all cases, the reliability of erosion coastal benches, platforms, and strand flats as sea-level indicators will depend mainly on the identification and understanding of the processes which were active in the development of these coastal features.

Purely wave-cut platforms are generally not datable. This can be a problem in areas characterized by very active tectonic movements, like Kikai Island, which is very close to the Ryukyu Trench (about 80 km) and where boundaries of terraces of different ages usually coincide with active faults, some of which also displace a single terrace (Figure 5). Relative sea-level changes may also produce multiple stepped benches. In this case, even ignoring the precise process of bench formation, a general rule to estimate sea-level change is to refer the inactive features, when possible, to the elevation of the present-day active counterpart (Figure 6).

Honeycombs, Tafoni, Pools, and Potholes

Honeycombs are small cavernous features assuming a cell-like structure. These patterns, which may be due to several physical processes, initially develop as many shallow depressions, but continued development produces deep chambers that are separated by thin walls of unweathered rock (Mustoe, 2005). Honeycombs have been reported as occurring in a variety of medium- to coarse-grained rocks, such as sandstones, granites, lavas, conglomerates, gneiss, schists, and limestone. Tafoni are cavernous weathering features of greater size (from a decimeter to several meters) developed on the rock surface. Since honeycombs and tafoni are typically found not only in coastal outcrops but also in inland deserts, their use as approximate sea-level indicators should always be confirmed by other kind of evidence.

Figure 6 A three-stepped bench can be observed at cape Plitri, on the west coast of Corfu Island, Greece. The elevation of the steps is +1.6 m, +0.8 m, and the present sea level (in the absence of wind, the local tidal range is almost negligible). Of the two raised benches, the uppermost one is partly jagged by wave projections and is related to a contemporary Holocene tidal notch that developed between at least 3030–2750 and 790–400 cal years BC, when a coseismic uplift of 0.8 m occurred. The intermediate bench (on which an observer is standing) developed since that time, until it was also uplifted coseismically at a more recent, indeterminate date. The third, lower bench is developing at the present sea level (Pirazzoli et al., 1994; photo D167, June 1991).

Erosion pools are flat-bottomed depressions, frequently found on limestone benches. They may result from solution and/or bioerosion processes in the mid-littoral and supralittoral zones. Elevated erosion pools on sheltered coasts can be used as indicators of past sea levels, with an accuracy of the order of the local tidal range, whereas on exposed coasts they only indicate former supralittoral areas in the reach of waves.

Erosion pools should not be confused with bioconstructed pools (see below).

Shore potholes are more or less rounded depressions, generally with greater depth than width, scoured by abrasion into a rocky shore, where sand, gravel, pebbles, and even boulders are circulated by wave motion. On exposed coasts, potholes may be formed at various levels, ranging from some meters above high tide to well below low tide; they are therefore inaccurate indicators of past sea-level positions.

Sea Caves and Arches

Sea caves are cavities excavated by marine erosion into a cliff in the range of wave action. Sea caves generally occur in the weaker parts of a rock formation, following soft layers, joints, faults, breccias, shale beds, unconformable strata, irregular sedimentation, or internal structures of lava flows. They are generally inaccurate sea level indicators. In limestone formations, however, sea caves are often of karstic origin, enlarged or reworked by the sea; their floor, if regular and flat, may be related to a former low tide position (Figure 7).

A sea cave opening to the sea on both sides of a headland, island or stack, beneath a connecting bridge, is a sea arch (Figure 8).

Figure 7 The floor of two abandoned sea caves extends to a bench at about 1 m above present sea level on the Yeditepe coast, south of the Orontes delta, Turkey. This bench was formed close to sea level, until it was uplifted by a coseismic uplift in the sixth century AD. This example shows clearly that the floor of sea caves cut into a hard limestone formation, which tends to the same level as the bench, may have a value as paleosea-level indicator similar to that of the nearby erosion bench (photo A745, May 1988).

Figure 8 Sea arches cut in a Miocene conglomerate at Cape Metsu in Tanabe Bay, Kii Peninsula, Japan. A double arch, called Megane-iwa (rock spectacles) is visible above a partially dissected bench resulting from a late Holocene sea level slightly higher than at present. The base of the two arches is at +3.6 and +2.8 m, respectively, above present m.s.l. (local spring tidal range: 1.46 m), suggesting that the arches have been formed at a slightly higher sea level. Below the higher arch, a third lower arch (not visible in the photo) exists. As the ceiling of its opening is at +0.1 m and the bottom at -0.9 m, it must be in formation at the present sea level (Takahashi, 1973; photo 553, April 1974).

Spurs, Grooves, Furrows, and Surge Channels

The occurrence of spur and groove systems has been reported from the upper part of the outer slope in most coral-reef areas. They consist of spurs a few meters high aligned more or less perpendicular to the reef front, alternating with almost bare grooves (Figure 9). The composite origin of these remarkable geomorphologic features (probably of growth for the spurs, erosion for the grooves) is still a matter of debate. Smaller-size furrows and surge channels into the outer bio-organic ridge of the reef occasionally extend grooves. Such features, when

Figure 9 Spurs and grooves are visible from the air near the southern reef of Takapoto Atoll, Tuamotus, French Polynesia (photo 5455, March 1980).

Figure 10 A series of straight surge channels, almost parallel to each other and perpendicular to the reef front, is partially emerged on the northern coast of Kikai Island (Ryukyus, Japan). Such emergence is not a normal feature and testifies of the recent uplift of the island, that has reached about 10 m in four steps occurred around 6065, 3250, 2700, and 1700 ^{14}C years BP, respectively (Nakata et al., 1979). The local tidal range is about 1.3 m and water level is at -0.3 m (photo 2214, November 1974).

recognized in fossil form, may be useful in the reconstruction of relative sea-level changes, though with a limited accuracy (± 1 m at best; Figure 10).

Bioeroded Holes

Borer organisms often leave morphological marks that can be used as sea-level indicators. As they can usually live at any depth in the sublittoral zone, they will indicate a sea level higher or equal than their marks and the same can be said for erosion features left by boring sponges (*Cliona*) and by sea urchins. However, when the elevated upper limit of burrows (e.g., of *Lithophaga* in the Mediterranean) is clearly defined

and forms a horizontal line, this corresponds to a former biological m.s.l. (Laborel and Laborel-Deguen, 1994), which can even be dated by radiocarbon assay when the articulated shells of the burrowing animals have been preserved inside the burrows.

Sea-urchin niches are small, rounded pools, that have been excavated by sea urchins at any depth in the sublittoral zone. When found emerged, such niches give evidence of relative sea-level fall, but confusion should be avoided with similar small basins that may have a meteoric origin or correspond to an initial phase of erosion pool development.

Depositional Features Associated with Erosion Marks

Though erosion features often make possible the estimation of past sea-level positions, they are usually insufficient to provide age estimates, for which adequate organic datable remains are essential. Fortunately, some depositional processes that contribute to shape certain geomorphic sea-level indicators can leave datable remains.

Marine Terraces

A marine terrace is any relatively flat surface of marine origin, bounded by a steeper ascending slope on one side and by a steeper descending slope on the opposite side. Marine terraces may result from marine abrasion or denudation (marine-cut terraces, or shore platforms, see Figure 5), or consist of shallow water to slightly emerged accumulations of materials removed by shore erosion (marine-built terraces), or also have a polygenic origin, with occurrence of *in situ* deposits after an abrasion phase (Figure 11).

In glacio-isostatically uplifting regions, small glacio-marine deltas situated near the margin of retreating ice sheets may be

Figure 11 A wide, flat marine terrace extends for many kilometers east of Chah Bahar, Iran, especially between Beris (photo) and the Pakistani border. This terrace is bordered landward by a series of higher marine terraces. It is an abrasion Pleistocene terrace at about +40 m, cut into Tertiary marls and capped by a 1–3 m thick layer of organogenic sandy limestone of coastal environment (panchina), containing marine shells and other debris cemented by calcium carbonate. Still undated (except than by radiocarbon estimates ≥ 28 ka), it can be ascribed tentatively to the last Interglacial cycle or to a polycyclic late Quaternary period (photo E123, May 1994).

preserved as flat surfaces related to the sea-level position at the time of their development (Andrews, 1986; Figure 12).

The occurrence of a series of stepped marine terraces usually results from eustatic changes in sea level superimposed on a tectonic trend. Uplifted terraces that act as a continuous tape recorder, each step developing when the rising sea level overtakes the rising land, may be most useful for Quaternary environmental studies, since each terrace can be considered as a fossil counterpart of the present-day terrace, platform, or reef flat. In seismic areas, however, terrace steps may have a tectonic origin (Figure 13).

When the uplift rate is sufficiently rapid (>1 mm year⁻¹), each major marine terrace may correspond to a different interglacial period or stage. In this case, ages increase with elevation, the upper levels also being the less well preserved. For slower

Figure 12 The lower five islands delta (Bay of Fundy, Canada) is a glacio-marine delta, dated 14–13 ka BP, which was subsequently uplifted by glacio-isostatic movements (photo A553, July 1987).

Figure 13 Five Holocene terrace steps can be observed on the northern coast of the Beagle Channel, at Playa Larga near Ushuaia (Argentina). In each of the four lower steps (marked 1–4), shell debris corresponding to beach deposits provided age estimates of about 405 years BP for terrace 1 at +1.6 m, 3095 years BP for terrace 2 at +3.8 m, 4335 years BP for terrace 3 at +5.2 m, and 5615 years BP for terrace 4 at +7.5 m (Gordillo et al., 1992). A clear relative sea-level fall occurred during the Holocene. According to the stepped pattern, coseismic uplifts with a return time of the order of 1.5 ka can be deduced for this area relatively protected from storm surges. Spring tidal range is 1.24 m (photo D77, November 1990).

uplift rates, major marine terraces may have a polycyclic origin, with sea level coming back at the terrace level after a period of exposure to weathering.

The age of a Pleistocene terrace is generally deduced from radiometric dating of marine organisms collected in growth position. U-Series and electron spin resonance (ESR) are the most frequently used dating methods for Pleistocene marine terraces, and radiocarbon for Postglacial and Holocene terraces. From a geomorphologic point of view, the best sea-level indicator of a terrace is the limit between the upper part of the terrace and the adjacent cliff base, especially if it is marked by a notch, because it can be correlated with the peak of the corresponding eustatic transgression. Its accuracy as sea-level indicator depends on the local tidal range and exposure to wave action.

Marine deposits left in uplifting regions by a tsunami (like the tsunami produced 7.1 radiocarbon ka by the Storegga Slide on Northern Europe coasts) may provide accurate stratigraphical indicators, enabling the estimate of the change in the relative sea level since the tsunami event (Smith et al., 2004).

Correlations between marine terraces and sea-level changes have been attempted for the last 300 ka in Papua New Guinea (Chappell, 1983), the last 400 ka in Barbados (Schellmann and Radtke, 2004), the last 680 ka in New Zealand (Pillans, 1983), and even the last million years in Sumba Island, Indonesia (Pirazzoli et al., 1993).

Algal Rims, Microatolls, Trottoirs, Cornices, and Surf Benches

Algal rims are reef-like structures developing on the outer edge of reef flats (mainly Porolithon) or on the rocky substrates on coasts subjected to regular wave action (Laborel, 2005). On reef flats, algal rims generally produce a slightly higher ridge, easy to recognize morphologically. In subtropical areas, algal rims (mainly Neogoniolithon) may contribute, together with the vermetid *Dendropoma*, to the development of trottoirs and even of microreefs growing up to sea-level, where they tend to extend laterally. They are very accurate (up to ± 0.1 m) sea-level indicators and easy to date by radiocarbon. Uplifted fossil forms enable detailed studies of algal-rim evolution in relation to sea level (Figure 14).

Microatolls are circular organic reef structures (diameter 1–6 m) consisting of a slightly raised rim built by coral (usually *Porites*), algae, vermetids, and other organisms surrounding a shallow depression on the shore or on a coral reef (Bird, 2005). When found in elevated position, in areas where moating phenomena are not possible, coral microatolls are excellent indicators of former low tide level (Figure 15).

Bioconstructed pools should not be confused with erosion pools. In the former, the walls of the basins are bioconstructed by vermetids or calcareous algae at the uppermost limit of the sublittoral zone (Figure 16). When preserved, elevated bioconstructed pools are excellent paleosea-level indicators, easy to date with radiocarbon, with an accuracy of up to ± 0.1 m.

The term trottoir, French for sidewalk, designates a simple crust of vermetids or calcareous algae, up to several centimeters thick, covering a rocky substratum, and forming a continuous, almost horizontal passage at sea level, one to several meters wide, between the rocky coast and the sea (e.g., see Figure 14). It is an erosion feature partly shaped by bioconstruction,

Figure 14 A coseismic uplift affecting all the western part of Crete (Greece) occurred in the fourth century (probably on 21 July 365) AD. At Damnoni, on the south coast of the island, the vertical displacement was of about 1.6 m. Algal reefs and trottoirs were suddenly emerged. Since that time, new algal reefs have developed at the present sea level. A comparison between the elevated and the active reefal and morphological counterparts gives evidence of the excellent accuracy of this kind of sea level indicator (photo G479, June 2000).

Figure 15 These two microatolls of *Porites* in growth position on the barrier reef of Bora Bora (Society Islands, French Polynesia) show, with ± 0.1 m accuracy, a former spring low tide position about 0.8 m higher than at present, that lasted until less than 2 ka (Pirazzoli and Montaggioni, 1988; photo 7666, October 1982).

because vermetids or calcareous algae that protect the substratum against further marine erosion rapidly cover the rocks at sea level. It is a very accurate (up to ± 0.1 m) sea-level indicator easy to date by radiocarbon.

The term trottoir has also been used in the literature to designate a purely bioconstructional overhang up to some decimeters wide (that should more appropriately be called a cornice), that is, a narrow intertidal reef construction made by *Lithophyllum*, *Dendropoma*, coralline algae, and also ostraids occasionally. Trottoirs are relatively frequent in the Mediterranean and in the tropics. Cornices have been reported from even wider areas. They are both excellent sea level indicators, especially in microtidal areas, and have been widely used to reconstruct and date relative sea-level changes or uplift movements during the Holocene, especially in seismic areas.

Figure 16 The outer rim of these active pools with microatoll shape is formed by *Dendropoma* and other vermetids, which are regularly wetted by waves on the front of the fringing reef of Tubuai, Austral Islands, French Polynesia. Local tidal range is 0.6 m and water level is near m.s.l. (photo 7855, October 1983).

Figure 17 Active surf bench cut into Quaternary reef limestone at 0.5 m above the high tide level near Cape Ara, Okinawa, Japan. Local tidal range is 1.7 m and water level is 0.3 m below m.s.l. (photo 6590, February 1981).

A special case is that of surf benches that occur mainly on limestone coasts exposed to persistent surf action. Here organic incrustations may develop on the floor of a tidal notch or near the outer edge of a bench, protecting the substrate rock and thus, locally inhibiting erosion. While erosion will proceed above the accretion level, a surf bench will begin to form, and may become several meters wide (Figure 17). Surf benches as high as 2 m above high tide level have been reported in the literature but are not horizontal; their elevation reaches the highest levels on the most exposed sites of headlands, declining when wave action decreases (Focke, 1978). As with erosional benches, reference to the present-day counterpart in the same place is useful, when possible, to assess relative sea-level changes (e.g., Figure 14).

Reef Flats, Coral Conglomerates, Beachrocks, and Speleothems

A reef flat consists mainly of a pavement cemented by calcareous algae and incorporating various detrital elements (coral

Figure 18 Boundary area between the active reef flat and a coral conglomerate flagstone about 1 m high at Temoe Atoll, Gambier Islands, French Polynesia. In this remote and presently uninhabited island, close to the southernmost limit of coral-reef growth in the South Pacific, a relative sea-level fall of about 0.8 m took place during the last 2 ka. In the case of Temoe Atoll, petrological analysis was not necessary to define the position of the former spring low tide level, because this level was locally marked by an almost horizontal fissure at about 0.5 m above the present m.s.l., separating the ancient reef flat with corals in growth position from the above conglomerate flagstone (Pirazzoli, 1987; photo 7470, October 1982).

fragments, Foraminifera, and *Halimeda*). A reef flat is initially the top of a reef framework, exposed to the atmosphere at low spring tides. In a second episode, skeletal detritus, torn away from the outer reef by storm waves, fills in depressions and irregularities in the reef framework. Lithification of the resulting coral conglomerate usually starts in the subtidal zone, the intergranular spaces being gradually occluded with marine phreatic (water in the zone of saturation) cements. When the deposits reach the intertidal zone, intergranular cements mainly occur in the form of marine vadose (above the zone of saturation, in the zone of aeration) types. When elevated reef flats still contain reef organisms in growth position, a former spring low tide level can be deduced from their surface. On the other hand, when they consist of coral conglomerate (Figure 18), an accurate estimation of the relative sea-level change usually requires petrological analysis. The method of investigation (Montaggioni and Pirazzoli, 1984) consists of sampling vertical sections at several levels and identifying the sections on the former environment (marine phreatic or marine vadose) of the first generations of intergranular cements. Once the boundary between the two former environments of cementation has been determined, the amount of relative sea-level change can be easily estimated from the difference in level between this boundary and the present low tide position.

The term beachrock applies to beach sediments deposited within the intertidal zone and cemented by calcium carbonate, especially in warm waters (Russel and McIntire, 1965; Figure 19). A beachrock is generally a good indicator of sea-level (with a vertical uncertainty depending on the tidal range). However, radiocarbon ages of beachrock samples should be interpreted with caution, because they may be reworked deposits, older than the beach lithification.

Figure 19 Elevated slabs of beachrock partly colonized by vegetation on the southern coast of Tunisia near Lella Meriem, north of Zarzis, testify of an intertidal zone higher than at present. Holocene emergence, probably of hydro-isostatic 5000 ^{14}C years BP, gradually declining afterwards to the present situation (Morhange and Pirazzoli, 2005). Water level is at high tide. Beach deposits near this level have been dated about 2000 years BP (photo G878, November 2002).

Speleothems from karst systems submerged by the sea can also provide former sea-level indications, especially when they are capped by a marine biogenic cover: the U-series dating of the outer part of the speleothem at a certain depth will indicate that the sea-level was still below that depth at that time, whereas the date of the beginning of the marine bioconstruction will approximate the time when the sea rose above the biogenic overgrowth. With this kind of indicator, useful late Pleistocene sea-level reconstructions have been provided from Florida, the Bahamas, and recently also from the Mediterranean (Antonioli et al., 2004).

Sedimentary Indicators of Relative Sea-Level Changes – High Energy

J A G Cooper, University of Ulster, Coleraine, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction: Definition of High-Energy Coasts

Coasts exposed to high levels of wave energy are routinely termed 'high-energy coasts.' Precise definition of the term is difficult, however, as the distinction between high- and low-energy coasts is entirely relative. For example, the coasts of Washington and Oregon experience higher levels of wave energy than neighboring California, although all of these would be viewed as high-energy environments in comparison with the sheltered coastline of Chesapeake Bay. In common usage, the term is used to distinguish wave-exposed coastlines (typically those facing the open ocean) from wave-sheltered coastlines (those found in embayments, back-barrier lagoons, semi-enclosed seas, and similar settings). Because of the high levels of wave energy being dissipated on such coasts, fine-grained sediments (clay and silt) are rare and deposition is usually limited to sand, gravel, and boulders.

High-energy coasts may contain relict deposits of low-energy settings that have now become exposed through coastal reorientation and/or sea-level changes (e.g., back-barrier sediments exposed on the foreshore). These features will not be considered here. Instead, the discussion will focus on those sedimentary features formed under high-energy conditions that provide an indication of sea level during their formation.

Often the sediments of high-energy coasts are exposed in association with those of contemporary adjacent low-energy sediments (e.g., washovers deposited into lagoonal muds). In such circumstances, the organic-rich sediments of sheltered environments are usually favored for the study of former sea levels because of their close relationship to particular tidal levels, the lower vertical range of dynamic activity (see below), and the abundance of dateable *in situ* organic material.

Nondepositional high-energy coasts may also contain sedimentary indicators of former sea levels in the form of erosional features produced by wave action and occasional coarse-grained sediments in coastline reentrants. Organic deposits occur on some low-latitude, high-energy coasts in the form of coral reefs.

Sedimentary processes and the resulting depositional or erosional features on high-energy coasts are highly variable in time and space. In order to relate Quaternary deposits to the sea level at which they were deposited, studies of contemporary sedimentary environments are necessary in order to identify the past environment of deposition and its relationship to present sea level.

Sea-Level Indicators on High-Energy Coasts

In assessing the record of past sea level, any potential indicator must exist in a known or predictable relationship to sea level at the time of deposition. If a chronological framework is to be

established it must also contain some dateable material incorporated within the sediment. For ancient sedimentary deposits to be correctly interpreted, a lithofacies model is therefore required.

A feature of high-energy coasts is that sedimentary environments may extend from many meters below to many meters above contemporary sea level ([Figure 1](#)), thus potentially reducing the vertical precision of sea-level indicators in this environment. Most sedimentary activity takes place in the zones of wave energy dissipation, particularly in the surf and swash zones. These zones, however, migrate laterally and vertically according to the nature and degree of wave energy being delivered to them. A surf zone typically becomes wider and extends further seaward during a storm compared to more typical conditions. The associated surf zone sediments would also be expected to adjust accordingly. Extremes of sedimentary activity in the vertical dimension are associated with very high-energy events (frontal storms, hurricanes, and tsunami).

The distance below sea level to which coastal deposition extends depends on wavelength (longer waves produce sediment movement at greater depths) while the landward extent of sedimentation is linked to wave run-up, which may be dramatically increased during storms. Thus, care must be taken in interpreting the origin of sedimentary deposits on high-energy coasts as storm or fair-weather-related features. In some instances, it has not been possible to unambiguously assign a storm, tsunami, or fair-weather origin to such deposits (e.g., [Switzer et al., 2009](#)). For example, controversy exists regarding the interpretation of the Hulopoe Gravels on Molokai, Hawaii, as normal shoreline sediments or a tsunami deposit ([Dawson and Shi, 2000](#)).

The large vertical range of activity also means that past indicators of former sea levels may occur within the range of contemporary coastal processes. This renders them vulnerable to modification by erosion or contemporary deposition. In a review of previous studies of supposed raised coastal landforms in eastern Ireland, [Carter \(1983\)](#) concluded that there was no unequivocal evidence of a higher than present sea level: all the features described lay within the range of modern storm activity and alternative explanations (surge, high waves, and tidal range changes) existed for all the cited evidence of higher than present sea-level features in earlier studies.

In contrast, high-level storm-related deposits are formed above the range of most contemporary processes and therefore have an enhanced preservation potential. It is thus important to distinguish them from deposits of more typical energy conditions. While salt marsh deposits are often regarded as good indicators of tidal levels in low-energy settings, [Cooper and Power \(1993\)](#) identified active salt marsh deposits on a high-energy rock coast at levels up to 9 m above contemporary sea level, where they were sustained by a combination of freshwater seepage and salt spray from large waves.

Figure 1 Indicative distribution of coastal depositional environments in relation to tidal reference levels.

Figure 2 Cross-shore distribution of sedimentary facies in relation to wave energy zones on a barred sandy coast. Reproduced from Davidson-Arnott RGD and Greenwood B (1976) Facies relationships on a barred coast, Kouchibouguac Bay, New Brunswick, Canada. In: Davis RA (ed.) *Beach and Nearshore Sedimentation*, pp. 149–168. Tulsa, OK: SEPM, Special Publication No. 24.

Shoreface-Inner Shelf Facies

Identification of former sea level thus relies on the identification of sediments deposited in a known relationship to sea level at the time of deposition. A number of classic studies of the 1970s and early 1980s (e.g., Clifton et al., 1971; Davidson-Arnott and Greenwood, 1976; Shipp, 1984) described the sedimentary facies of contemporary coastal deposits (primarily barred and nonbarred sand beaches) in different environmental settings at varying scales of resolution. The deposits of these systems typically extend from the subaerial dune and back beach, across the shoreface to the inner shelf. The model of Clifton et al. (1971) related the sedimentary facies of the nearshore environments primarily to the degree of asymmetric flow produced by shoaling waves in the nearshore zone. In deeper water, small ripples dominated the seabed, while in the zone of wave attenuation, large bedforms were produced before waves actually break. High current velocities produced planar sand facies in the breaker zone itself and in the surf zone another zone of large bedforms existed. Swash action at the

intertidal beach was associated with planar, seaward-dipping bedding. Shipp (1984) identified distinctive upper shoreface, longshore trough, longshore bar, landward slope bar crest and seaward slope facies on the shoreface of a high-energy coast. These were followed seaward by a transition to the inner shelf (coincident with fair-weather wave base). Davidson-Arnott and Greenwood (1976) presented a detailed facies description of barred environments, subdividing them into bar crest, seaward slope, landward slope, and trough. Each facies had a distinctive suite of physical and biogenic sedimentary structures that was repeated at each bar (Figure 2).

From these site-based studies, generic models of shoreface-beach sedimentary facies were developed that comprise lower, mid, and upper shoreface, foreshore, overwash, and dune facies (Moslow, 1984). Although not explicit in this regard, these accounts of the nature of sedimentary facies in various depositional subenvironments provide a basis for assessing the relationship between a sedimentary facies and sea level during its deposition. The arrangement of facies can be used to

Figure 3 Comparative facies of barred (a) and nonbarred (b) sand beaches in relation to contemporary sea level. Reproduced from Hunter RE, Clifton HE, and Phillips RL (1979) Depositional processes, sedimentary structures and predicted vertical sequences in barred nearshore systems, southern Oregon coast. *Journal of Sedimentary Petrology* 49: 711–726.

Figure 4 Relationship to sea level of various sedimentary structures on Netherlands beaches (based on information in Roep, 1986).

identify the type of depositional environment (Figure 3) and its relationship to others but it cannot readily identify the precise relationship to former sea level with accuracy better than a few meters.

Roep (1986) explicitly explored the relationship between beach sedimentary characteristics and sea level at three barrier beaches in the Netherlands. This was done using temporal analysis of profile variability on modern beaches coupled with careful assessment of contemporary sedimentary facies and individual sedimentary structures (Figure 4). A number of sedimentary indicators were noted to have a close relationship to contemporary sea level. The high water swash limit, for example, was found to be the best lithological marker in relation to sea level. This separates the seaward-dipping foreshore laminae from the landward-dipping backshore.

The study by Roep (1986) does not necessarily have universal applicability: the extent of specific features is likely to

vary from site to site depending on tidal range, wave climate, beach morphology, etc. The elevation of swash run-up, for example, will vary according to modal wave conditions and beachface gradient and composition. Nevertheless, the approach indicates the potential for refining estimates of former sea-level position from high-energy coasts by studying contemporary facies in equivalent settings.

Inlet-Associated Facies

Inlets on barrier-lagoon coasts contain a distinctive arrangement of sedimentary facies that may be preserved as an inlet migrates (Moslow, 1984). A number of studies have shown that inlet-associated sediments occupy substantial portions (up to 40%) of barrier-associated sedimentary records (Moslow, 1984). Because inlets are dominated by tidal currents which operate within a relatively fixed elevation range relative to the

Figure 5 Inlet-associated sedimentary facies compared with transgressive and regressive facies arrangement on a sandy coast (based on Moslow, 1984).

tidal frame, the identification of particular inlet facies can be an aid in assessing past sea level.

Commonly, three sedimentary facies are associated with tidal inlets: the inlet floor, inlet channel, and spit platform (Figure 5). The inlet floor typically comprises a coarse lag deposit, the channel cross-bedded coarse sand and shell, and the spit platform, low angle, planar cross-bedded parallel laminations of sand and shell. The spit platform develops in the intertidal zone and is thus the best indicator of sea level. The channel facies relate to the size of the tidal prism and the erodibility of the underlying substrate and not specifically to sea level.

Gravel and Boulder Beaches

Coarse-grained beaches, which dominate glacial and paraglacial coasts as a result of erosion of gravel and boulders from diamictons, differ fundamentally from sand beaches in that their high permeability and high infiltration rates reduce surface flow, particularly of backwash. This eliminates or reduces the potential for seaward return of sediments and induces a net landward movement of gravel systems. Orford et al. (1991) provide a review of the characteristics of coarse-grained beaches in the context of Quaternary sea-level change. Coarse-grained barriers are therefore more likely to preserve a record of landward movement of sediment under high-energy conditions than of sea-level changes. The sedimentary facies of gravel beaches are less well studied than sand beaches, although Bluck (1967) presented a facies model based on grain shape and packing that enables identification of varying depositional environments on gravel beaches.

Rock Coasts

Erosional processes on high-energy rock coasts produce a range of features that potentially relate to sea level. The essential element of rocky coasts is the cliff-shore platform couplet in which a retreating cliff is associated with a remnant shore platform left behind as the higher part of the cliff is eroded. The relationship of shore platforms to sea level is highly variable and they have been noted to occur intertidally, supratidally, and subtidally, depending on the cliff lithology and the level and nature of wave activity operating on it.

Similarly, caves cut by waves that exploit zones of weakness and remnant sea stacks and arches all form close to sea level but have variable relationships to it. As sea-level indicators, they have a very large vertical error margin (several meters). Marine notches occur on cliffed coasts as a result of wave abrasion, biological processes, and chemical processes. Pirazzoli (1986) identified three types of notch in relation to sea level. Supratidal notches develop in the wave spray zone above high water. Their precision in identifying former sea level is relatively low. Subtidal notches may develop though bioerosion at a particular level and they may, if the life range of the responsible organisms is known, be more closely indicative of sea level. While intertidal notches can be formed by wave-induced erosion, on the more exposed parts of the coast they form at variable heights above sea level. These and several potential biogenic indicators including barnacle lines and corals, enable estimates of former sea level to be made with centimeter-scale accuracy (Pirazzoli, 1986).

Beachrock

Beachrock (Figure 6) is a carbonate-cemented sandstone that forms on the shoreline of tropical and warm temperate beaches. It can form relatively rapidly (within a few hundred years) and therefore provides a good potential indicator of sea-level position (Hopley, 1986). It is widely distributed on high-energy beaches around southern Africa, the Caribbean, and Australia. Its position within the intertidal zone renders beachrock a potentially good indicator of former sea level, particularly, if the tidal range is small. However, the precise levels at which beachrock forms are not well known and this reduces its potential vertical accuracy as a sea-level indicator Kelletat (2006). Hopley (1986) summarized the potential shortcomings of beachrock as a sea-level indicator: misidentification of true beachrock (it is often associated with aeolianite), the need to use the uppermost level of the beachrock and the possibility of derived shell material in whole rock radiocarbon age determinations. To these can be added the potential for slumping of whole blocks after deposition and reworking of old beachrock and incorporation into younger deposits. This underscores the need for additional facies analysis in assigning an indicative sea level. Nonetheless whole rock beachrock

Figure 6 Beachrock is common on warm temperate to tropical coasts. Beachrock at Umhlanga Rocks, KwaZulu-Natal province, South Africa (a) contains diagnostic lower beachface sedimentary structures (trough cross-bedding) and trace fossils. Shallowly submerged beachrock on the Datça Peninsula, Turkey (b) preserves a former shoreline position. Beachrock cementation can incorporate coarse beach clasts as well as sand as in this example (c) from Goana Island, British Virgin Islands.

dating was used to develop a high-resolution late Holocene sea-level curve for South Africa (Ramsay, 1995). Thomas (2009) used OSL dating of beachrock to avoid issues related to diagenesis in India. The early formation of beachrock has the added advantage for sea-level studies of lithifying and thus

preserving shoreline facies that might otherwise be eroded or migrate under a rising sea level (Cooper, 1991).

Sedimentary Response to Sea-Level Change

On depositional coasts, the sedimentary response to changing sea level is mediated by a range of important factors. Sediment supply can determine whether a depositional sequence accumulates. Under falling sea-level conditions this can lead to a distinctive series of laterally extensive shoreline facies. Even under rising sea level, an abundance of sediment can lead to an advancing shoreline (Roy et al., 1994). Sediment type has been noted to vary between terrigenous during lowstands and carbonate during highstands as fluvially incised valleys are drowned and terrigenous input is trapped in drowning valleys during transgression (Stolper et al., 2005).

The accommodation space, as mediated by antecedent topography, is a vital factor in determining the nature of any sedimentary sequence. It controls the availability of space in which sediments can accumulate and the capacity of accumulated sediments to be preserved. A particular aspect of the antecedent topography is the basement slope over which the plane of sea-level migrates. If steep, lateral migration rates will be slower, providing more time for development of shoreline equilibrium forms and slower rates of increase in accommodation space. If gently sloping, migration rates will be faster and shoreline features are more likely to be stranded on the shelf under transgression or on the coastal plain under regression. As the sea-level changes, so too will the accommodation space and the influence of inherited topographic features (Roy et al., 1994).

Because of the variability of these factors, there is, thus, to be expected a variable response to an apparently uniform sea-level change. Added to this, the rate of sea-level change itself is also an important determinant of coastal sedimentary response. Despite this complexity, a number of simplified models of shoreline response to changing sea level have been presented.

Orford et al. (1991) presented a model of gravel barrier platform evolution in response to changing sea level. The responses were mediated by sediment supply, accommodation space and rate of sea-level rise. A series of potential evolutionary paths were identified and sedimentary responses included barrier breaching, sealing, rollover, accretion, erosion, and overstepping.

Carter (1988) identified three simplified models of coastal profile response to sea-level rise (Figure 7). In the erosional response model, sediment eroded from above sea level is envisaged being transported seaward and retained on the shoreface where it enables the nearshore profile to be maintained. Such a model requires an erodible bluff at the rear of a beach that yields sand-sized material suitable for beach building. A similar theoretical construct is involved in the 'Bruun Rule' of shoreline erosion, a now-dated approach that has been shown to be a poor predictor of actual shoreline response (Cooper and Pilkey, 2004). Under the rollover scenario, the coastal barrier sediment volume is maintained, largely unchanged by the process of barrier overwashing of sand from the shoreface. Thus, translation of the barrier takes place as an essentially intact feature in a landward direction

Figure 7 Three simple modes of response to sea-level rise. Reproduced from Carter RWG (1988) *Coastal Environments*. Cambridge: Cambridge University Press.

across the underlying basement slope. Barrier island migration has been documented along much of the US east coast. The third model 'barrier overstepping' is envisaged to occur when a beach is unable to respond to rapidly rising sea level by migration of erosion and is consequently drowned in place and preserved. Because of their slower morphological response times to sea-level rise, the probability of *in situ* drowning is higher for gravel than sand barriers (Carter, 1988).

These three models likely represent end-members or extreme cases. It is likely that combinations of their elements constitute the situation in nature. More sophisticated geomorphic-stratigraphic models of shoreline response to rising sea level have been developed (Roy et al., 1994; Stolper et al., 2005). While each of the models makes simplifying assumptions, they enable shoreline behavior under changing sea level to be simulated numerically and compared with observed sedimentary records in order to investigate the importance of the various controls outlined above.

Van Goor et al. (2003) assessed the potential response of tidal inlets to rising sea level and concluded that an inlet could persist if sedimentation within the inlet-associated environments kept pace with sea level. If not, the inlet could be drowned. Former inlets of the Netherlands Wadden Sea were believed to have been drowned during the Holocene transgression by sea-level rise rates of over 0.8 m per century.

Sedimentary Indicators of Relative Sea-Level Change: Transgression and Regression

There are abundant sedimentary records of trends in former sea-level trend. While these may not provide a precise estimate of sea level at a given time, they indicate the direction of relative sea-level movement. The sequence stratigraphy approach to sea-level change (see article in this volume) is based on the balance between the changing accommodation

space for sedimentation and the rate of sediment supply with which that space may be filled. Thus the vertical stacking of sedimentary facies and the nature of the contacts between them can be interpreted in the context of sea-level change. An account of the principles and application of sequence stratigraphy is provided elsewhere in this volume.

Transgressive situations occur over wide areas when sea-level rises. Local transgressive sequences can also be produced when shortages of sediment promote coastal erosion and consequent landward migration of the shoreline. Identifying regional and local patterns in coastal sequences is thus important in determining the nature of the driving forces of change. Regressive situations can occur where there is a regional fall in sea level that reduces accommodation space and causes a seaward migration of the coast. A similar regression can be caused by a local abundance of sediment. In the latter scenarios, a coastline can continue to accumulate sediment and extend seaward even under conditions of sea-level rise if there is an abundance of sediment. The essential characteristic of transgressive stratigraphic sections is the deposition of progressively deeper water facies over shallower water facies, whereas in regressive stratigraphies the reverse is the case (Figure 8). Investigations of transgressive and regressive stratigraphies in Australia (Roy et al., 1994) show a somewhat more complex range of preserved sequences that reflect differences in accommodation space, sediment supply, and antecedent topography. Transgressive sequences varied from preserved barriers where the substrate slope is gentle and transgressive sandsheets where the slope is steeper. In regressive situations, with adequate sediment supply, strandplains are formed that prograde seawards over shallow marine deposits.

There are, however, a variety of other sedimentological indicators of sea-level change. For example, Marchant and Flemming (1978) described granite boulders on a beach on the wave-exposed Cape Coast of South Africa. The nearest source area was offshore in 20 m water depth. Current velocities

Figure 8 Transgressive and regressive barrier sequences. Under transgressive conditions (a), sea-level changes are associated with landward transport of sediments and stacking of deeper water over shallower water facies. Under regressive conditions (b), falling sea level is associated with seaward advance of the shoreline and vertical stacking of shallow water facies over deeper water facies. Both situations depicted depend on adequate sediment supply. Compare to [Figure 9](#) in which the preservation potential of sequences under different sediment supply rates is considered.

required to move such boulders from the source area were over 9 m s^{-1} , far beyond the range of velocities produced by even extreme waves at contemporary sea level. Current velocities in the surf zone velocities, however, would be capable of transporting such boulders. It was concluded that the boulders had been carried landward during transgression as the surf zone migrated landward during the Holocene sea-level rise.

[Dunbar and Barrett \(2005\)](#) assessed the sediment distribution on modern continental shelves in relation to bed shear stress and water depth. They found consistent trends in high-, medium-, and low-wave energy settings and applied the approach to Pliocene deposits where the paleobathymetry (and hence sea level) could be estimated if assumptions were made regarding the past wave climate.

Preservation Potential

Under regressive conditions the preservation potential of shoreline facies is relatively high since the progressive lowering of energy concentration in the tidal frame gradually leaves the deposits and landforms stranded above all but the most energetic waves. These features may be eroded or reworked under storm action at lower sea levels. Their preservation potential is much enhanced if they are buried by subsequent deposition of, for example, sand dunes, or protected from subsequent modification by the formation of more seaward beachridges.

The preservation potential of transgressive shoreline facies in relation to the rate of sea-level change was assessed by [Davis and Clifton \(1987\)](#) ([Figure 9](#)). Those authors concluded that under slowly rising sea level, the potential existed for almost total destruction of the transgressive coastal sequence and formation of an erosional surface or ravinement surface on which subsequent marine deposition would take place.

Under a rapidly rising sea level, however, the potential for *in situ* preservation of progressively shallower sediments was much higher and a full vertical sequence of deep to shallow water facies might be preserved.

Quaternary High-Energy Shorelines and Sea-Level Indicators

A number of studies of Quaternary sediments in high-energy settings have utilized knowledge of contemporary facies to identify past sea-level positions. Sea level is the plane around which the energy of coastal forces is distributed. Typically, the rates of sea-level change (mm year^{-1}) are much smaller than the interannual, seasonal, or even diurnal variability in the vertical levels at which coastal processes operate (m-vertical scale). Consequently, the identification of the role of sea-level change itself is difficult to ascertain in the sedimentary record of high-energy coasts.

Interpretation of coastal response to sea-level change at decadal to centennial timescales is difficult because the sedimentary response due to sea-level change is often masked by responses to short-term fluctuations in energy, sediment budget adjustments, and morphological evolution ([Cooper and Pilkey, 2004](#)). Working at the centennial scale, however, [Orford et al. \(1995\)](#) established a strong relationship between the retreat rate of a swash-aligned (i.e., with negligible long-shore drift) gravel barrier in western France and historical sea-level rise rates. It is more typically at the millennial timescale on high-energy coasts that sedimentary indicators are used to reconstruct sea-level history. For example, [Murray-Wallace \(2002\)](#) assessed the history of sea level in South Australia over the past 11 interglacials by studying the facies of raised beach features (usually barriers and dunes) in southern

Figure 9 Preserved sequences in a transgressive situation under low, intermediate and rapid sea-level rise. Reproduced from Davis RA and Clifton HE (1987) Sea-level change and the preservation potential of wave-dominated and tide-dominated coastal sequences. In: Nummedal D, Pilkey OH, and Howard JD (eds.) *Sea-Level Fluctuation and Coastal Evolution*, pp. 167–178. Tulsa, OK: SEPM, Special Publication No. 41.

Australia. The levels of vertical resolution were in the order of a few meters. A number of studies have been made of cemented and unconsolidated Quaternary sediments in high-energy coastal settings. Their success in deducing former sea levels depends on clear identification of facies or erosional features associated with depositional environments with a specific relationship to sea level.

Roep and Beets (1988) utilized knowledge of the distribution of diagnostic sand barrier sedimentary structures (Roep, 1986) in relation to sea level (deepest dry eolian sand, highest marine burrow, range of low-angle bars, range of structureless sand, highest high angle bar, highest clay lamina, and highest ripples) in combination with dating of contained articulated shells to trace the mid-late Holocene sea-level history in the western Netherlands. Following the same reasoning, Van Heteren et al. (2000) utilized optical dating of sandy sediments at the beach–dune sedimentary interface to track sea-level changes on a coastal barrier in Massachusetts. The well-defined contact between dune and beach facies was taken as an indicator of former sea level (~2.3–2.7 m above mean spring high tide under contemporary conditions). The sea-level curve derived from dating of the basal dune sands coincided closely with a curve derived from organic deposits in an adjacent marsh, supporting the contention that this particular indicator had remained in a constant relationship to sea level over a few thousand years. The contact between aeolian and foreshore deposits was similarly used to track late Holocene sea-level rise in Alabama (Rodríguez and Meyer, 2006).

Former sea levels associated with raised gravel beach shorelines in western France were assessed by facies mapping and comparison with modern equivalents in the immediate vicinity (Haslett and Curr, 2001). A last interglacial transgressive sequence associated with rapid sea-level rise was preserved as it was overstepped by sea level. This was overlain by a prograding sequence that developed during a prolonged stillstand of sea level accompanied by an abundant sediment supply.

Through facies analysis and interpretation of the diagenetic history of emergent beachrock near Durban, South Africa, Cooper and Flores (1991) identified sediments of the surf zone, breaker zone, swash zone, back beach, and dune that gave an approximation of the sea-level position at which they formed. A rock platform cut into this lithified unit and an associated boulder beach facies recorded a later sea-level position. Both sets of beach facies were interpreted to have been deposited between +4 and +5 m above present mean sea level.

Working on the rocky coast of Banks Peninsula, New Zealand, Bal (1997) assessed a number of features (shore platforms, sea caves, sea stacks, notches, and cliffs). He identified a set of features related to contemporary sea level and a higher set of similar features at 5–6 m above their contemporary equivalents. These were associated with a last interglacial shoreline, whose level could be determined if it was assumed that wave energy conditions were similar during the last and present interglacials.

In now-submerged settings, direct observation of sediments associated with former sea levels is more difficult. Terrestrial

sediments are often dredged from the seabed, indicating that sea level was formerly lower but *in situ* investigations are necessary to identify former indicators of sea level. Consequently, much use has been made of seismic stratigraphic approaches to interpret sea-level history, often accompanied by underwater coring. A number of studies of lower than present sediments on the continental shelf have indicated the presence of discrete sedimentary units that are out of context in their present setting. These include drowned deltas (Barnhardt et al., 1997), spits, barriers, and beaches associated with lowstands of sea level (Stea et al., 1994). Barnhardt et al. (1997) described submerged deltas off large rivers in the Gulf of Maine that developed during lower than present sea-level stands (Figure 10). The deltas were identified on the basis of their internal structure and on their composition. They are composed mainly of sand and exist in a setting where contemporary mud deposition is the dominant process.

Recent advances in high-resolution multibeam echosounding have revealed many examples of drowned coastal geomorphic forms that indicate the positions of former shorelines. These are best preserved when RSL rise is rapid or when the shoreline deposits have been lithified (Figure 11). On the shelf of South Africa and Australia are several lines of submerged beachrock and aeolianite ridges that mark former shorelines (Cooper, 1991; Roy et al., 1994). Gardner et al. (2005, 2007) document and illustrate a variety of such features from the Florida continental shelf including deltas and barrier islands that closely resemble landforms on the contemporary west Florida coast. The dating of these deposits, however, remains problematic.

Combined analysis of emerged and submerged sedimentary deposits can enable a clear understanding of the processes and patterns of deposition and help decipher the relationship between different sedimentary units and their preservation.

Figure 12 Diagram showing sequence of deposition in relation to higher and lower than present sea levels in the Gulf of Maine. Reproduced from Shipp RC, Belknap DF, and Kelley JT (1991) Seismic stratigraphic and geomorphic evidence for a sea-level lowstand in the Northern Gulf of Maine. *Journal of Coastal Research* 7: 341–364.

Working in the northern Gulf of Maine, an area affected by substantial isostatic uplift following deglaciation, Shipp et al. (1991) undertook a combined study of onshore and offshore coastal deposits that recorded deposition between relative sea

levels between 70 m above and 60 m below the present and spanning glacial to contemporary temperate climatic conditions (Figure 12). Recently, a combination of high-resolution multibeam bathymetry, seismic stratigraphy, seabed coring,

and radiometric dating enabled Kelley et al. (2010) to record submerged shorelines and associated deposits during a period of prolonged sea-level stability in the Gulf of Maine when the shorelines were sites of human occupation.

Sedimentary Indicators of Relative Sea-Level Changes – Low Energy

R J Edwards, Trinity College Dublin, Dublin, Ireland

© 2013 Elsevier B.V. All rights reserved.

Introduction

Relative sea-level (RSL) change is the result of variations in ocean level (eustatic) and vertical land movements (isostatic). Throughout the Quaternary, both eustatic and isostatic changes have accompanied the waxing and waning of large, high latitude, continental ice sheets. The RSL changes experienced at locations around the globe are predominantly influenced by proximity to these ice sheets, and generalized patterns of RSL change can be predicted on the basis of geographical location and ice-sheet history. The most detailed records of RSL currently available are concerned with changes that have occurred since the end of the last Quaternary glaciation ~11 000 years ago, during the Holocene.

RSL changes are reconstructed from physical features and biological organisms whose distributions are related to sea level in a consistent manner (see [Lambeck et al., 2010](#)). Information concerning RSL change can be extracted from geomorphological evidence (e.g., wave-cut platforms and tidal notches), or from sedimentary environments and their associated flora and fauna. Sea-level data from these diverse sources have produced RSL records from locations around the globe.

This article examines the evidence for RSL change that is contained within low-energy sediments. It begins by outlining the principal, low-energy coastal environments that are sources of RSL data. It then considers the nature of the sea-level information they contain, and the methods employed to generate and analyze these data. It examines the relative strengths and weaknesses of these methodologies, highlighting recent developments and areas of current research interest.

Low-Energy Sedimentary Environments

Low-energy coastlines are common in regions around the globe where waves and tides are small and currents slow. They are typified by accumulations of fine-grained sediment (silty sand to clay) that accrete to form intertidal flats with distinctive floral and faunal communities. The lowest-energy environments are typically found in small, sheltered embayments, lagoons, and estuaries with restricted fetch ([Woodroffe, 2002](#)). Local hydrodynamic conditions may also give rise to low-energy environments in certain parts of an inlet, such as in the lee of a higher-energy gravel spit or sand bar. While most common in these protected areas, lower-energy sediments can also be found along open coasts where large tidal ranges promote the accumulation of extensive intertidal flats that dampen wave action. Some examples of low-energy sedimentary environments are illustrated in [Figure 1](#).

Sources of Sea-Level Data

The lithological and biological characteristics of low-energy intertidal sediments are intimately linked to the tidal frame. As a consequence of their position at the interface between

land and sea, intertidal zones exhibit strong environmental gradients. The highest elevations at the upper limit of tidal influence are associated with terrestrial organisms that can withstand periodic inundation by saline waters, or marine organisms that can withstand prolonged periods of subaerial exposure. As elevation decreases (hydroperiod increases), environmental conditions change, and plant and animal communities alter until almost marine conditions are reached at the lowest tidal levels. This vertical zonation related to tide level means that RSL information can be extracted from intertidal sediments. This is achieved by analyzing the nature of the sediments themselves (e.g., grain size, organic content, elemental/isotopic composition) and the plant and animal remains preserved within them.

Characteristic Intertidal Environments

Intertidal environments can be broadly subdivided into low elevation, unvegetated tidal flats, and higher-elevation vegetated surfaces. Tidal flats are commonly low-relief accumulations of sand, silt, and clay that are covered by most high tides. These flats may be dissected by tidal creeks, the size and density of which are related to the tidal range ([Allen, 2000](#)). While sediment source varies with location, in low-energy environments most material is redistributed across the intertidal flats by gentle wave action and tidal currents. The deposition of finer-grained sediments is facilitated by flocculation and biological packaging (e.g., production of fecal pellets). Similarly, the cohesive nature of clay sediments, coupled with consolidation due to escaping pore water and binding by organisms (e.g., algal mats), reduces the subsequent remobilization of deposited material.

The accumulation of sediment elevates intertidal surfaces, reducing the depth and period of tidal inundation. When sufficiently high relative to the tidal frame, these surfaces become vegetated. At this point, minerogenic sedimentation is augmented by the additional supply of organic material from above and below ground production ([Allen, 2000](#)). The presence of vegetation tends to slow currents and dampen waves, permitting the accumulation of more fine-grained sediments. Vegetation may also serve to bind intertidal sediments, reducing their propensity for erosion and transport. Together, these processes promote the accumulation of characteristic high-elevation organic-rich deposits. The nature of the organic-rich sediments will vary depending on the vegetation communities they support. In high to middle latitudes, saltmarsh plants occupy these high-elevation environments, while toward the tropics, mangrove swamps become widespread ([Bird, 2000](#)).

Saltmarshes

The floral character of a saltmarsh reflects a number of factors such as location, local hydrographic conditions, salinity regime, substrate, and elevation relative to the tidal frame ([Allen and Pye, 1992](#)). In many areas, the general stages of

Figure 1 Some examples of low-energy sedimentary environments. (d) Open, low-energy mudflats fronting a mangrove swamp in Indonesia © Photograph, Horton BP.

saltmarsh evolution outlined in [Figure 2](#) can be recognized, although the precise species involved and their links to tidal levels may vary. Low-elevation sediments are first colonized by pioneer species such as *Spartina* and *Salicornia* ([Figure 2\(a\)](#)). A saltmarsh dominated by these environments is referred to as being youthful or immature ([Frey and Basan, 1985](#)). As the saltmarsh develops, the vegetated platform increases in elevation and reduces in gradient as sediments infill the available accommodation space ([Figure 2\(b\)](#)). A mature or old marsh has a larger proportion of taxa associated with high-elevation environments, such as *Puccinellia* and *Phragmites* species.

[Figure 3](#) shows three examples of contrasting saltmarsh environments. Minerogenic saltmarshes ([Figure 3\(a\)](#)) are typical of low-energy coasts around northwest Europe. The organic content of their sediments and the preservation of plant material are much less than in organogenic saltmarshes such as those encountered on parts of the eastern coast of North America ([Figure 3\(b\)](#)). Finally, [Figure 3\(c\)](#) shows a wide, flat expanse of saltmarsh accumulating behind a mangrove swamp in southeast Australia. This region has experienced a general encroachment of mangrove communities into saltmarsh areas in recent years. The cause of this environmental change may be due to a number of factors, including changes in RSL, tidal prism, sedimentation, and surface elevation ([Rogers et al., 2005](#)).

Mangroves

In tropical regions, saltmarsh vegetation is largely replaced by mangrove communities ([Figure 4\(a\)](#)). Mangrove trees grow best in low-energy environments with muddy substrates and can form extensive fringes where tidal ranges are large ([Bird, 2000](#)). They share a number of features in common with the saltmarsh systems outlined above. The presence of mangroves traps sediment suspended in tidal waters, promoting accretion and elevating the sediment surface. Low-elevation surfaces are characterized by pioneering species such as *Avicennia*, pictured in [Figure 4\(b\)](#) with its pneumatophores protruding from the adjacent unvegetated intertidal flats. As the sediment surface elevation increases, these pioneers are replaced by other mangrove species such as *Rhizophora*.

The Utility of Low-Energy Sedimentary Environments

The use of intertidal environments in sea-level research stems from the fact that subenvironments can be distinguished on the basis of their sedimentary character (lithostratigraphy) and associated flora or fauna (biostratigraphy); and that these subenvironments can be linked to the tidal frame ([van de Plassche, 1986](#)). Traditionally, attention has been focused on the easily recognizable transition between marine and

Figure 2 A sketch of the evolution of a typical minerogenic saltmarsh. (a) Pioneer species colonize unvegetated intertidal flats, enhancing sediment accumulation and promoting infilling of available accommodation space. Low-marsh species dominate, and the saltmarsh is referred to as immature. (b) Sediment accumulation results in an elevated saltmarsh surface and an expanded platform colonized by high-marsh species. An increased proportion of high-marsh environments indicates a mature saltmarsh. MHWST = mean high water of spring tides. MHWNT = mean high water of neap tides.

terrestrial conditions which is expressed in the lithostratigraphy by the interchange of minerogenic and organic-rich deposits (e.g., [Tooley, 1978](#)). The age of organic, peaty deposits can be established by radiocarbon dating, permitting a chronology for the sedimentary sequence to be developed (chronostratigraphy). In recent years, advances in the methods used to discriminate between subenvironments (e.g., microfossil analysis) and improvements in dating techniques (e.g., accelerator mass spectrometry (AMS) radiocarbon dating, and short-lived radionuclides such as ^{137}Cs , ^{210}Pb , etc.) have expanded the range of sedimentary contexts from which RSL data can be extracted.

In comparison with their higher-energy counterparts, low-energy sedimentary environments are less susceptible to processes such as erosion and transport. Given sufficient sediment and accommodation space, it is possible for relatively unbroken sequences to accumulate, and these provide ideal sources of RSL data.

Despite their potential utility, the records of RSL change preserved within these sequences are not always straightforward to extract. While sea-level studies are inherently concerned with extrinsic controls on saltmarsh development, marsh morphodynamics will inevitably involve a wider range of phenomena which can also leave imprints in the sedimentary record (e.g., autocyclicity; [Singh Chauhan, 2009](#)). This reinforces the fact that the sequences themselves do not comprise direct measurements of sea level, but rather record changes in a number of proxies for sea level. These proxies are influenced by other factors in addition to RSL change and therefore represent composite signals that require deconvolution. Consequently, the resulting records

will be affected by the particular indicator used, the capacity of that indicator to register change, and the preservation of this signature in the geological record. This will, in turn, depend on a number of factors including the magnitude and rate of RSL change, the sensitivity and precision of the indicator used, and the successive environmental conditions experienced after its incorporation into the sedimentary sequence.

Reconstructing RSL Change From Low-Energy Sedimentary Environments

A variety of strategies and methodologies are employed to distil RSL signals from the composite records contained within low-energy sediments. These are all underpinned by the multiproxy approach, employing a combination of litho-, bio-, and chronostratigraphic data. Lithostratigraphy is usually determined from a series of sediment cores collected at a study site and described in the field ([Figure 5](#)). In some circumstances, lithostratigraphy may also be examined in exposed sections ([Allen and Haslett, 2002](#)). Selected cores or monoliths are then returned to the laboratory for further analysis. This analysis may include quantitative sedimentology (e.g., grain size or loss on ignition), geochemical assessment (e.g., stable isotopes and elemental ratios of organic carbon and total nitrogen), and micropaleontology (e.g., pollen, diatoms, or Foraminifera) to establish the nature of the environment in which the sediment accumulated. The age of sediment samples is then commonly inferred by radiocarbon dating the organic material they contain.

Sea-Level Indicators

An ideal sea-level indicator will be related to sea level in a consistent and quantifiable manner. In this way, changes in the indicator can be used as proxies for changes in RSL (Pirazzoli, 1996). For example, the altitude of past RSL can be inferred from a sediment sample if the current altitude of that sample is known, and if the environment in which it

formed has a quantified vertical relationship to sea level. Quantifying this vertical relationship (termed the indicative meaning) is important to account for the differing vertical distributions of coastal subenvironments and associated sea-level indicators (van de Plassche, 1986). Figure 6 illustrates the components of an indicative meaning which are defined in relation to the tidal frame. Any unquantified change in tidal range through time will introduce vertical error into RSL reconstructions. Samples from low-energy sedimentary environments are used to reconstruct RSL change in two principal ways: (1) by attempting to fix the vertical position (altitude) of sea level relative to a geodetic datum and (2) by examining switches in depositional environment indicating an increase or decrease in marine influence. A selection of approaches to RSL reconstruction that employ one or both of these perspectives are illustrated below. Detailed descriptions of these approaches, along with their associated errors and limitations are discussed in van de Plassche (1986), Shennan (1986), and Tooley and Shennan (1987).

Sea-Level Index Points

An established methodology for reconstructing vertical changes in RSL from sedimentary environments has been developed as part of several International Geosciences Programme (IGCP) Projects (Tooley, 1985). This methodology uses sea-level index

Figure 5 (a) Lithostratigraphic data is commonly collected in the field using hand-corers. points (SLIPs) that fix the altitude of former RSL in time and space (Shennan, 1986). In order to be established as a SLIP, a sediment sample must possess information concerning its location (latitude and longitude), altitude (relative to a leveling datum), age (commonly inferred from radiocarbon dating), and its indicative meaning (Figure 6).

Figure 6 A sketch showing the components of an indicative meaning. The indicative range describes the vertical interval over which a sea-level indicator is found. The indicative difference describes the position of the mid-point of that indicative range (called the reference water level) relative to a defined tidal level. In this example, the reference water level is MHWST + 0.1 m, and the indicative range is ± 0.2 m.

Traditionally, SLIPs have been established from lithostratigraphic contacts between terrestrial and marine sediments, with supporting microfossil data (e.g., pollen, Foraminifera, and diatoms) being used to delimit the onset or removal of brackish/marine conditions and to confirm that the contacts are conformable (Shennan, 1986; Tooley, 1985). This focus on a restricted set of depositional environments arose because of the need to establish an indicative meaning (derived from the nature of the lithostratigraphy above and below a contact) and the requirement for organic material suitable for radiocarbon dating. The lithostratigraphic change from terrestrial peat to marine mud is referred to as a transgressive contact, while the switch from marine mud to terrestrial peat is termed a regressive contact. Transgressive and regressive contacts indicate an increase or decrease in marine influence, respectively. They are used as purely descriptive terms that do not imply an underlying cause or process. For example, a regressive contact (intertidal mud to terrestrial peat) may arise from the accumulation of sediment with or without a change in RSL.

Considerable attention has been directed toward quantifying the magnitude of uncertainty associated with determining the age and altitude of a SLIP (Shennan, 1986). For example, in the case of the age of a SLIP, these may relate to the uncertainties inherent in calibrating radiocarbon dates, or may be associated with contamination by allochthonous carbon (e.g., rootlet penetration). Additional errors can be introduced if the lithological contacts from which dateable material is recovered are associated with breaks in sedimentation, erosion, or reworking. In the traditional lithologically based scheme, the SLIP approach requires contacts to be conformable so that up-core changes reliably reflect the transitions between spatially adjacent subenvironments (Shennan, 1986). This may be difficult to establish from sedimentology alone and can be a particular problem for transgressive contacts where reworking mixes material to produce ‘pseudotransitional’ deposits (Waller et al., 2006). For these reasons, supporting data (e.g., biostratigraphy) are required to demonstrate that the dated sample forms part of a sequence of change extending across the contact but not restricted to it.

While biostratigraphy is the preferred tool for elucidating variations in marine influence across lithological contacts, poor microfossil preservation can result in insufficient data to reliably determine the nature of environmental change. In recent years, there has been growing interest in potential alternative geochemical approaches to supplement the

information provided by biostratigraphy. The isotopic signature of bulk organic carbon ($\delta^{13}\text{C}$) and the elemental ratio of organic carbon and total nitrogen (C/N) are routinely used to examine the source of organic matter in coastal and estuarine environments. In many cases, a good correlation exists between salinity and $\delta^{13}\text{C}$, suggesting that isotopic signatures can be used to distinguish between terrestrial, brackish, and marine environments (e.g., Yu et al., 2010). In regions where C3 and C4 plants occupy different saltmarsh elevation zones, the potential exists to recover an isotopic fingerprint of this biological zonation, although inputs from allochthonous carbon and/or diagenetic changes (e.g., decomposition) can distort these signatures (see Kemp et al., 2010). In the future, compound-specific analyses may provide one means of avoiding the complication of in-washed material (e.g., Johnson et al., 2007; Tanner et al., 2007).

Where C4 plants are absent from saltmarsh environments, the combination of $\delta^{13}\text{C}$ and C/N ratio has been used to detect relative shifts in marine influence on the basis that tidally introduced (allochthonous) particulate organic carbon will decrease with increasing elevation (see Lamb et al., 2006; Wilson et al., 2005). In this case, it is the trends in $\delta^{13}\text{C}$ and C/N ratio rather than the precise values which are considered diagnostic, with particularly marked excursions being associated with the upper limit of marine influence. While further work is needed to better understand the role of complicating factors, geochemical signatures have the potential to provide information on RSL change in Holocene sediments (Lamb et al., 2007). However, at present, the resulting SLIPs will be associated with larger vertical error terms than those produced by microfossil-based reconstructions due to the difficulties of precisely quantifying sample-indicative meaning.

Uncertainties relating to reliably establishing indicative meaning are not the only potential sources of vertical error associated with SLIPs. In addition to altitude errors that may be introduced during fieldwork (e.g., leveling to a datum, measuring depth in core, etc.), perhaps the most significant unknown variable is the extent to which samples may have been lowered through time due to autocompaction of the sediment column (Allen, 2000). In general terms, the effects of compaction are most pronounced in organic-rich sequences and will have greatest impact on the altitudes of SLIPs established from the transgressive contacts of thick, intercalated coastal peat deposits. At present, there is no agreed protocol for dealing with the effects of sediment compaction, although its effects are widely recognized (e.g., Horton and Shennan, 2009; Long et al., 2006a,b; Törnqvist et al., 2008; van Asselen et al., 2009). While a range of approaches have been used to investigate and address its impacts (e.g., Brain et al., 2011; Edwards, 2006; Massey et al., 2006; Paul and Barras, 1998), an initial assessment can simply be made by distinguishing between SLIPs from differing stratigraphic contexts (see Horton and Shennan, 2009).

In light of these collected uncertainties, SLIPs are plotted on age-altitude graphs as individual data points with associated error bars. The magnitude of these error terms are an important limiting factor in determining the maximum resolution at which RSL changes can be measured using this methodology. SLIPs fix the former altitude of RSL in time, but do not provide any information on the nature of sea-level change between

points. As a result, the number, distribution, and quality of data points provide fundamental constraints on the detail with which patterns of RSL change can be reconstructed.

An example of the age-altitude approach

To illustrate the SLIP approach, a hypothetical sedimentary sequence with associated radiocarbon dates is presented in Figure 7. The lithostratigraphic section (Figure 7(a)) is typical of the intercalated low-energy sedimentary sequences found beneath minerogenic saltmarshes in northwest Europe (Allen, 2000; Long et al., 2000). The type of litho- and chronostratigraphic data furnished by a transect of sediment cores is shown in Figure 7(b) and these data are used to produce an age-altitude plot (Figure 7(c)). For simplicity, in this example, all transgressive and regressive contacts are assigned an indicative meaning equivalent to the elevation of MHWS ± 0.5 m.

In addition to the SLIPs, two dated samples without indicative meanings are included on the diagram. While these cannot be directly linked to a former RSL, given knowledge of their depositional environment, they can be used to define the limit of possible RSL altitude (and are thus referred to as limiting dates). In this example, one limiting date is derived from the base of a terrestrial peat (Core E) and must have accumulated above the limit of marine influence (RSL below). Conversely, a second limiting date is taken from subtidal sediments in the same core (RSL above). These dates can be used to constrain the band of sea-level change drawn around the scatter of SLIPs (Figure 7(c)).

The age-altitude plot in Figure 7(c) exhibits a number of features typical of these kinds of record. Data are not evenly distributed through time with the result that there are intervals of 1000 years or more for which no sea-level data are available. Where data coverage is good, vertical scatter is introduced by differential sediment compaction. This is evident by the tendency for intercalated SLIPs (open boxes) to plot below basal SLIPs (filled boxes) of similar age. For example, a large amount of compaction in Core E is responsible for the scatter of points around 1000 BP. Finally, the calibration of radiocarbon dates results in age uncertainties of differing magnitude, and this produces SLIPs with variable age errors. In reality, many of the SLIPs would also be associated with differing altitude errors. The combination of these limitations means that a generalized band of RSL change is plotted around the data. The thickness of this band defines the upper limit of resolution at which the record can be reliably interrogated.

A variant of the age-altitude approach

A modified version of the SLIP methodology has been employed to extract sea-level data from isolation basins. These rocky basins may be located along high-energy coasts, but contain sedimentary sequences that have accumulated in low-energy conditions, protected from the open sea behind a rock sill (Figure 8). Classic examples of isolation basins are found along coastlines experiencing long-term crustal uplift (e.g., Greenland, Scandinavia, Scotland). This uplift results in RSL fall and the isolation of these sedimentary basins from marine influence (Figure 9). This isolation is recorded by microfossil assemblages (e.g., diatoms, Foraminifera) that are sensitive to changes in salinity. These microfossils are preserved within isolation basin sediments and record changes from marine

Figure 7 An example stratigraphic sequence used to furnish sea-level index points (SLIPs) for age–altitude analysis. (a) A cross-section of the hypothetical lithostratigraphy indicating the location of a transect of boreholes. (b) The lithostratigraphy as represented by six boreholes, with associated chronological data provided by a series of hypothetical radiocarbon dates. (c) The resulting age–altitude plot of SLIPs plotting changes in mean sea level over time. The height and width of the boxes represents the altitude and age uncertainties associated with each SLIP. Mean high-water spring tides (MHWST) is defined as 2 m above mean sea level. All SLIPs were assigned an indicative meaning of ± 0.5 m. Two limiting dates (without indicative meanings) are shown as triangles.

through brackish to freshwater depositional environments (Figure 9).

In rapidly uplifting areas (e.g., Greenland), this isolation occurs comparatively quickly and is recorded in the litho- and biostratigraphy by an abrupt isolation contact. This contact can be dated and used as a SLIP, although the altitude of the index point is reconstructed differently from those established in saltmarshes. Instead of using the altitude of the sediment

Figure 9 A schematic diagram showing the isolation of a tidal basin by falling relative sea level. (a) The basin is inundated at all stages of the tide, and marine sediments accumulate. (b) The basin is isolated from the sea at low tides and brackish conditions are experienced. (c) High water is now below the height of the sill and the isolation basin becomes a freshwater lake.

sample, SLIPs from isolation basins use the altitude of the lowest part of the rock sill separating the basin from the open sea (Figure 9). In this way, isolation basins have provided important, long records of RSL change from regions close to former centers of ice loading. While these index points are not susceptible to the influence of sediment compaction, their reliable interpretation relies on successfully locating the lowest point of the sill and assumes that the sill itself is impermeable to seawater. Figure 10 shows a simplified example of data collected from an isolation basin study in western Greenland (see Long et al., 2006a,b for details). A transect of boreholes were recovered from an isolation basin with a sill 1.61 m above modern sea level (Figure 10(a) and 10(b)). A series of diatom samples were taken across the transition from a marine gray silt clay into a freshwater gyttja, and an AMS radiocarbon date from this contact returned an age of 4150 ± 50 BP (Figure 10(c)). These data were used to establish a SLIP which, when plotted on an age–altitude diagram with other SLIPs from the area, charts RSL change over the last 8000 years (Figure 10(d)).

Figure 10 Example of sea-level data from an isolation basin in western Greenland. (a) Plan of the isolation basin showing transect location and position of sill. (b) Lithostratigraphy of the isolation basin showing sample core location. (c) A simplified stratigraphic column plotted with a summary of the diatom analysis, which shows the shift from polyhalobous species (indicative of marine conditions) to oligohalobous species (associated with freshwater conditions). (d) An age–altitude plot derived from isolation basin data collected in western Greenland (example site data plotted as a filled box). Figures compiled and adapted from Long et al. (2006a).

In regions associated with smaller amounts of uplift (e.g., northwest Scotland), complete isolation from the sea takes much longer with the result that brackish water, transitional sediments accumulate in greater thicknesses, and stratigraphic contacts are less abrupt. This complicates the identification and interpretation of the isolation contact and ongoing research is focusing on improving reconstructions from these transitional environments, either by a more sophisticated treatment of microfossil data, or by additional isotopic/elemental analysis (e.g., Mackie et al., 2007).

Sea-Level Tendencies

An alternative and complementary perspective to age–altitude analysis can be supplied by considering the timing and nature of changes in depositional environment. Instead of attempting to quantify vertical RSL movements, attention is focused on

delimiting periods of time when sea-level indicators from a particular area display increases or decreases in marine influence. Increases in marine influence are termed positive sea-level tendencies, while decreases in marine influence are called negative sea-level tendencies (Shennan, 1986).

Sea-level tendencies have been defined, employed, and (mis)interpreted in differing ways in the literature, which has led some authors to suggest that the terms are potentially misleading and no longer helpful (Allen, 2003). If they are to be used with sedimentary archives, it is important to recognize that sea-level tendencies are the product of a balance between sedimentation and local tide-level changes and consequently are not synonymous with rises and falls in RSL. While in mature marshes or settings with well-quantified sedimentation rates, they can provide insights into changes in the rate of RSL rise, even similar tendencies observed across a region need not be related to RSL change. For example, in southern Britain, rapid

colonization by *Spartina anglica*, a hybrid saltmarsh grass capable of withstanding long periods of submergence, produced dramatic increases in sediment accumulation and saltmarsh growth throughout the region during the early part of the twentieth century (see Allen, 2000 and references therein). This gave rise to a widespread negative sea-level tendency during a time in which instrumental measurements indicate rising RSL.

While it should therefore be used with caution, the tendency approach can help tackle certain limitations inherent with age–altitude analysis. For example, in some instances SLIPs from closely spaced transgressive and regressive contacts in the same core are indistinguishable on an age–altitude plot, resulting in a loss of stratigraphic information (e.g., Core B in Figure 7). However, these contrasting SLIPs will be clearly distinguished by tendency analysis. Tendencies can also be useful in identifying inflections in the RSL curve when dealing with SLIPs from isolation basins, since these records are unaffected by variations in sedimentation rate. Another potential strength of the tendency approach is that it expands the range of material that can be used to provide sea-level information. All dateable indicators that show increases or decreases in marine influence can be considered, irrespective of whether their altitude or indicative meaning is quantified. Ultimately, in order to be successful, the tendency approach requires a large number of dated indicators, and this, coupled with its inherent ambiguities, may be one of the reasons why it is not widely applied in sea-level studies.

Marsh Elevation Diagrams

Improvements in microfossil-based reconstructions of RSL have increased the accuracy of indicative meanings and expanded the range of sediments that can be employed in sea-level studies. A new generation of sea-level curves is seeking to combine detailed marsh elevation diagrams with precise SLIPs. These records are of sufficient resolution that they can be compared with proxy climate data, or combined with tidal records (Horton and Edwards, 2006). This type of approach is currently being developed to investigate the relationship between climate and sea level at multidecadal to centennial scales (e.g., Gehrels et al., 2005, 2006, 2008; Kemp et al., 2009, 2011). The use of marsh elevation diagrams (sometimes called paleoenvironmental curves) was developed in the organogenic marshes of the eastern USA (e.g., Varekamp et al., 1992). Multiple sediment samples are collected from individual cores, and the microfossils (commonly Foraminifera) contained within them are used to precisely fix the former elevation of the sediment surface relative to the local tidal frame (Figure 11(a)). The organic-rich nature of the sediments permits large numbers of radiocarbon dates to be collected for each core, and detailed accumulation histories can be developed (Figure 11(b)). By combining these two detailed datasets, the pattern of tide-level change through time can be determined, in this case shown as a curve of MTL rise (Figure 11(c)).

The marsh elevation diagram approach produces, in effect, a series of stratigraphically constrained SLIPs from a single core, with ages determined by its accumulation history. These records can be used to plot general changes in the altitude of RSL but are also capable of capturing more subtle variations in water level. In theory, while marsh elevation diagrams will vary

across a study site, reflecting the local balance between sediment accumulation and RSL (Figure 11(a)), when they are combined with detailed accumulation histories (Figure 11(b)), the same record of RSL change will be extracted (Figure 11(c)). In reality, a record may contain breaks in sedimentation or changes in rate that are not reliably captured by the available age data. In this event, the resulting pattern of RSL change may be distorted (Horton and Edwards, 2006). Consequently, the success of this approach requires a strong age framework (Edwards, 2004) and should incorporate a detailed program of lithostratigraphic investigation to ensure that the sample borehole is located in a position that captures the dominant environmental changes experienced at a site.

Given the importance of accurately determining accumulation history, attention is increasingly being focused on the construction of composite chronologies that employ a range of dating methods to infer the age of intertidal sediments. Approaches have employed various combinations of short-lived radionuclides (e.g., ^{210}Pb , ^{137}Cs , ^{241}Am), chronostratigraphic markers (e.g., tephra, pollen, spheroidal carbonaceous particles, lead isotopic signatures), paleomagnetism, and a range of techniques based around AMS radiocarbon dating (e.g., Gehrels et al., 2006a,b; Marshall et al., 2007, 2009). Increasingly sophisticated statistical manipulations of age data also have the potential to improve the development of age–depth relationships (e.g., Blaauw et al., 2007; Heegaard et al., 2005; Parnell et al., 2008; van de Plassche et al., 2001), although these will ultimately be limited by the fidelity of the sedimentary sequences themselves (Edwards, 2007).

Records produced using marsh elevation diagrams will also be susceptible to the influence of sediment compaction in a similar manner to intercalated SLIPs. Some studies remove the long-term RSL trend in their data, which reflects the overall influence of factors like glacio-isostatic movement and sediment compaction (e.g., Kemp et al., 2011). Other studies endeavor to decompact their records by incorporating age–altitude data from basal SLIPs (e.g., Gehrels et al., 2005).

Figure 12 shows an example record developed from replicate cores recovered from two saltmarshes in North Carolina, USA (Kemp et al., 2009). Marsh elevation reconstructions developed from a foraminiferal transfer function for tide level are combined with detailed chronologies derived from pollen analysis, short-lived radionuclides (^{210}Pb , ^{137}Cs), bomb-spike, and high-precision AMS radiocarbon dating. The resulting records, which exhibit similar patterns of change, show good agreement with data from neighboring tide gauges and extend these instrumental records back to AD 1500. Analysis of the long-term trends in records such as these can be used to examine the timing and magnitude of any recent acceleration in the rate of RSL rise. Ongoing research aims to produce multiple records of this sort with the ultimate aim of identifying common features that may reflect larger-scale, climate-related changes in ocean level (see discussion in Gehrels, 2010).

Concluding Remarks

Low-energy sedimentary environments and their biological components are rich sources of RSL information. Collections of SLIPs, which are predominantly sourced from low-energy

Figure 11 A hypothetical example showing the marsh elevation-diagram approach. (a) Marsh elevation diagrams produced from two cores at the same site. Marsh surface elevation is plotted relative to mean high water, which is 2 m above mean tide level. (b) Accumulation curves for both cores. The contrasting age–depth relationships reflect local differences in sediment accumulation rate. (c) Plots of MTL rise produced by combining the marsh elevation diagrams with the accumulation curves. The example demonstrates that the same RSL record can be extracted from both cores.

Figure 12 An example of high-resolution sea-level reconstruction developed for two sediment cores from North Carolina, USA. Reproduced from Kemp AC, Horton BP, Culver SJ, et al. (2009) Timing and magnitude of recent accelerated sea-level rise (North Carolina, United States). *Geology* 37(11): 1035–1038. Sample elevation was reconstructed from a foraminiferal transfer function for tide level. Sediment accumulation histories were developed with composite chronologies comprising a pollen chronohorizon, short-lived radionuclides (^{210}Pb , ^{137}Cs), and AMS radiocarbon dating (including the use of ‘bomb-spike’ and high-precision radiocarbon dating). The inset illustrates the good agreement between reconstructed RSL and the instrumental record from two neighboring tide gauges (see Kemp et al., 2009 for details).

sedimentary environments, enable the spatial patterns of RSL change to be established. In turn, these patterns are used to elucidate climate–ice–ocean relationships and the local scale processes that influence their expression in the sedimentary record (e.g., Engelhart et al., 2009; Horton and Shennan, 2009). The provision of reliable RSL data in the form of SLIPs plays a central role in glacial isostatic adjustment modeling and several efforts are underway to compile and disseminate databases of index points to facilitate this process (e.g., Brooks and Edwards, 2006; Brooks et al., 2008). Ongoing research seeks to improve the precision and resolution of existing RSL records and expand the range of environments from which sea-level data can be obtained. Advances in dating techniques, especially those involving minerogenic sediments and improvements in establishing sample indicative meaning, will help to bridge the gap between short duration instrumental records and longer-term geological reconstructions. Understanding sea-level rise and variability is a critical endeavor, both in terms of the range of scientific disciplines that use sea-level data and the wider societal issues associated with the impacts of future sea-level rise on our heavily populated coastlines (Church et al., 2010). While considerable uncertainty currently exists regarding the nature of this rise and its impacts, low-energy sedimentary environments will unquestionably play a critical role in future efforts to improve our understanding of sea-level change.

Coral Records of Relative Sea-Level Changes

Coral and Sea Level

Coral and coral reefs have played an invaluable role in the determination of past relative sea-level changes throughout the Quaternary at a range of time scales. Individual corals grow by calcification, their polyps secreting carbonate that is added to the exoskeleton of the colony. Coral polyps maintain a symbiotic relationship with species of dinoflagellate algae, called zooxanthellae. These limit the depth within which corals can survive to the photic zone (typically 0–30 m in clear tropical waters). Corals cannot tolerate more than very brief exposure when emerged above the water surface at lowest tides. Coral reefs are thus restricted to a depth range that varies from around mean low water, to depths at which water clarity limits photosynthesis (excepting cold-water corals found in high latitudes).

Coral reefs cover more than 250 000 km² of the earth's surface largely within the tropics where sea surface temperatures exceed 18 °C (Veron, 1995). The greatest diversity of corals occurs in the Indo-Pacific with a second region centered on the western Atlantic; reefs are absent from the Mediterranean and reef development is limited in the eastern Atlantic and eastern Pacific Oceans (Figure 1). The distribution of species across an individual reef, and of particular growth morphologies, varies according to depth, and in relation to several other environmental parameters such as wave energy, light availability, and sediment loading. Individual coral colonies can continue to grow for several hundreds of years, and after their death may be incorporated into the reef structure, together with other calcareous organisms such as Foraminifera, molluscs, and coralline algae. The reef fabric may be interpreted and the position of the surface of the sea during the time of coral growth can sometimes be inferred on the basis of species or growth form. The growth form of corals varies from delicate branching corals, through encrusting forms, to hemispherical colonies of massive corals. Large colonies of coral contain various geochemical records of conditions reflecting ambient water chemistry experienced during their growth. Such proxy reconstructions recovered from modern living corals have been correlated with, and extend, instrumental and historical records, whereas fossil corals provide an archive of water chemistry conditions at previous times during the Quaternary. Those corals that have been particularly constrained by exposure within the intertidal zone, provide the clearest evidence of former sea levels, particularly if it can be demonstrated that the coral is in growth position.

The role that reefs play in reconstructing sea level is comprehensively reviewed by Hopley et al. (2007, chapter 3), Montaggioni and Braithwaite (2009, pp. 405–428), and in numerous entries in the *Encyclopedia of Modern Coral Reefs* (Hopley, 2011). This article examines the contribution that coral records have made to the reconstruction of Quaternary sea level at four different time scales. First, the value of coral for

the recognition and dating of interglacial sea-level highstands reconstructed from terraces of reef limestone is described, particularly on uplifted shorelines throughout the tropics (Figure 2(a)). Second, the pattern of postglacial sea-level rise determined from drilling the foundations of modern reefs is examined, indicating the broad coincidence of reconstructions from disparate sites. Third, and in contrast, the role of coral in clarifying the variability of relative Holocene sea-level curves along tropical shorelines in the far-field (i.e., remote from former ice sheets), recording variability of record at different sites, is outlined. Finally, the potential of intertidal corals, called microatolls, to track interannual sea-level variations is reviewed.

Quaternary Sea-Level Highstands

The significance of fossil reef limestone, emerged and forming terraces elevated above modern shorelines particularly around the Pacific Ocean, was recognized in the early twentieth century by Reginald Daly who realized that sea-level history provided further support for former Ice Ages that were recorded by moraines marking a series of glacial advances in Europe (Daly, 1915). The advent of suitable dating techniques made it possible to place these shorelines into a sequence based on age, discriminating Holocene from Pleistocene, and more recently, differentiating successive interglacial sea-level highstands. Fossil coral reefs have played an important role over recent decades in refining the history of these sea-level variations. A sequence of reef terraces on Barbados, and a more extensive series on the Huon Peninsula on the north coast of Papua New Guinea, contain corals, now elevated by uplift. Dates on these corals constrain the age of past shorelines.

Whereas Holocene corals can be dated using radiocarbon dating techniques (appropriate to determine ages within the past 40 000 years), Pleistocene corals are largely beyond the range of radiocarbon dating, and have been dated primarily by the uranium-series disequilibrium dating methods, supplemented by several other techniques such as electron spin resonance. U-series dating measures the accumulation of ²³⁰Th as a daughter isotope in the uranium decay chain over the past 500 000 years, and U-series and ¹⁴C date comparisons on corals have extended calibration of the latter technique (Bard et al., 1990). With the initial application of U-series dating, Veeh (1966) showed that there was widespread evidence throughout the tropics for a Last Interglacial shoreline around 120 000 years old at heights averaging 6 m above the present sea level. The islands and continental shorelines, such as Bermuda, Bahamas, Seychelles, and Western Australia, were considered stable. However, several of these island sites, such as Oahu in the Hawaiian Islands, are now considered to have undergone flexural adjustments in response to loading of the ocean floor by adjacent volcanic islands. Mangaia in the Cook Islands for example, together with Mitiaro (Figure 2(b)) and

Figure 1 Present-day distribution of coral reefs (based on [Veron, 1995](#)), showing location of key sites discussed in text: 1, Comoros Islands; 2, Seychelles; 3, Maldives; 4, Cocos (Keeling) Islands; 5, Christmas Island; 6, Abrolhos Islands; 7, Rottneat Island; 8, Ryukyu Islands; 9, Sumba, Indonesia; 10, Huon Peninsula, Papua New Guinea; 11, Guam; 12, Tonga; 13, Hawaiian Islands; 14, Tahiti; 15, Cook Islands; 16, Cayman Islands; 17, Haiti; 18, Bahamas; 19, Bermuda; 20, Barbados.

Figure 2 Pleistocene reef terraces indicating former highstands of sea level: (a) the northeastern corner of Christmas Island in the Indian Ocean, uplifted by flexure as it migrates over a bulge in the ocean floor prior to subduction into the Java trench, shows a series of terraces that mark former reefal shorelines, the lowermost of which is Last Interglacial in age; (b) the coast of Mitiaro in the southern Cook Islands which is composed of Pleistocene reef limestones that show a pattern of former grooves, mirroring, though at greater spacing to, the modern spur and groove which can be seen seaward of the fringing reef crest; (c) a sequence of two Pleistocene reef limestones on the neighboring makatea island of Mauke, also in the southern Cook Islands, the lower limestone was deposited during marine oxygen isotope stage 7 and the upper (the base of which is marked by the survey staff) is Last Interglacial in age (marine oxygen isotope substage 5e); (d) an erosional notch cut into Tertiary limestone (foreground) and the Last Interglacial reef limestone (indicated by the person in the background) marks a former highstand of the sea on Cayman Brac in the Cayman Islands – similar evidence is widespread throughout many of the islands in the West Indies, especially the Bahamas; (e) a similar reef limestone terrace characterizes the shoreline in Tonga in the Pacific Ocean (here shown on Lifuka in the Ha'apai group in central Tonga); and (f) the southernmost example of such a reef terrace occurs at Fairbridge Bluff on the island of Rottneat off the coast of Western Australia, where a reef existed during the Last Interglacial beyond the latitudinal limit to which present-day corals construct modern reefs.

Mauke (Figure 2(c)), are makatea islands comprising a volcanic interior but with a rim of limestone (makatea) that contains reef units that were formed during marine oxygen isotope stages 7 and 5. These reef units occur at different heights on the different islands as a result of differential rates of flexure in response to loading by the younger volcanic island of Rarotonga (Woodroffe et al., 1991).

Particularly useful have been those shorelines that have been uplifted on which there is a flight of raised reefs generally with the higher, and more landward, ones being older. Three such terraces occur above sea level on Barbados; more occur on the rapidly uplifted Huon Peninsula in Papua New Guinea. On the basis of dating of the Huon Peninsula terraces from several sites at which there have been different rates of uplift, a history of sea-level positions has been developed, and it has been possible to link this record with that of oxygen isotopes from deep-sea cores (Chappell and Shackleton, 1986). Figure 3 shows the sea-level curve derived from the Huon Peninsula and deep-sea core evidence. More terraces are found on those coasts that are uplifting rapidly, such as at active plate margins, including islands in Indonesia such as Sumba, along the coast of Japan including the Ryukyu Islands, and in the Caribbean, for example on the island of Haiti. With refinements in dating it has been possible to extend the chronology back to identify older interglacial reefs. Reefs associated with oxygen isotope stage 7 are now widely recognized (Figure 2(c)), and reef limestones associated with stages 9 and 11 have also been dated (Siddall et al., 2006). Diagenetic changes, particularly recrystallization of coral mineralogy (aragonite to calcite), impose constraints, but the advent of thermal ionization mass spectrometry (TIMS) U-series dating, and modeling of open system behavior based on isotope ratios, have enabled greater precision for age determinations on increasingly small samples (Thompson and Goldstein, 2005).

The record of sea-level highstands derived from radiometric dating of corals from Pleistocene reef limestones provides chronological support for control on the timing of ice-sheet growth and ocean volume variations through the superimposition of variations in the eccentricity, obliquity, and precession of the earth's orbit. More recently, it offers the prospect of resolving millennial-scale, suborbital oscillations of amplitude

10–15 m that appear overprinted on the longer-term oscillations (Figure 3). Such variations have been observed during glacial periods, 55–30 ka (Yokoyama et al., 2001), and appear within interglacial reef terraces such as those on Huon Peninsula, Oahu, and Barbados during oxygen isotope stage 5 (Thompson and Goldstein, 2005).

Figure 4 illustrates how the reef limestone terraces are superimposed in different ways on shorelines that are experiencing different rates and patterns of vertical movement. Whereas fossil shorelines are stretched out on uplifting coasts, they are superimposed on coasts that are stable, such that the Last Interglacial is generally the most prominent terrace (Figures 2(d), 2(e), and 2(f)). A one-dimensional forward computer spreadsheet model of reef growth based on a sea-level compilation like that shown in Figures 3 and 4 has been developed (Koelling et al., 2009). This enables simulation of the anticipated sequence of reefs in different tectonic settings. It produces stepped reef terraces that resemble those observed on Huon Peninsula and in other settings (Figure 5).

It is also possible to identify sequences of Pleistocene reefs on shorelines that have been subsiding. Coral atolls provide one example of such a setting and here carbonate layers have formed like icing on a cake, at periods when the sea has been high. Dating of successive highstands, separated by solutional discontinuities, constrains the pattern of subsidence (Figure 4). On the one hand, these sequences provide a record of sea-level stands, on the other hand, there is a need to establish the rate of coastal uplift or subsidence, and whether it has been constant.

Last Interglacial reef limestones are prominent from many sites in the tropics and there is an emerging consensus that they formed during a relatively stable period of sea level 2–6 m above present between 128 and 116 ka (Siddall et al., 2006). However, there is less agreement about the details of smaller oscillations, as indicated by reef growth, within that highstand. Several researchers have identified what appear to be multiple reef units within the Last Interglacial. Others, through comparison of constructional reef with erosional notches, have inferred that the interglacial culminated with a rapid rise of several meters such as could occur if the West Antarctic ice sheet collapsed (Blanchon et al., 2009).

Figure 3 A curve of sea level over the past 240,000 years derived from dating of raised reef terraces on Huon Peninsula correlated with the oxygen isotope record from deep-sea cores. Reproduced from Chappell J and Shackleton NJ (1986) Oxygen isotopes and sea level. *Nature* 324: 137–140. The curve has been derived by correcting the observed elevation of fossil corals for uplift using an uplift rate inferred from the height of the Last Interglacial shoreline. Evidence for a more detailed sequence of oscillations has been proposed on the basis of further dating of corals from Huon (large dots show samples used by Chappell et al., 1996, oscillations during glacial times, green line, is after Yokoyama et al., 2001). Recently, closer scrutiny of U-series ages and their correction for open system behavior has also implied oscillations during interglacial times (red lines). Reproduced from Thompson WG and Goldstein SL (2005) Open-system coral ages reveal persistent suborbital sea-level cycles. *Science* 308: 401–404.

Figure 4 Schematic representation of reef terraces on shorelines that have different histories of vertical movement. The inset shows a simplified version of the sea-level curve shown in [Figure 3](#), highstands identified with marine oxygen isotope stage 7 and substages 5e, 5c, and 5a are marked. The relative location of terraces representing those highstands on shorelines that are uplifting at an average rate of 0.5 m a^{-1} , stable, and subsiding at 0.1 m a^{-1} is shown, and can be compared with the modern reef that has developed during the Holocene.

Figure 5 A one-dimensional forward computer spreadsheet model of reef growth based on a sea-level compilation like that shown in [Figures 3](#) and [4](#) has been developed. This enables simulation of the anticipated sequence of reefs in different tectonic settings. It produces stepped reef terraces that resemble those observed on Huon Peninsula (illustrated) and in other settings (based on [Koelling et al., 2009](#)).

Postglacial Sea-Level Rise

At the Last Glacial Maximum, around 20 000 years ago, sea level was of the order of 120–130 m lower than present as a result of the volume of water that was locked up in ice sheets. Reconstruction of the shoreline at this time is largely derived from morphological evidence such as submerged cliffs and notches, and deposits of shallow-water shells. Reefs occurred along what were to become the foreslopes of modern reefs and these deposits are now largely unknown or inaccessible.

The pattern of ice melt and concomitant sea-level rise during the termination, however, has been reconstructed primarily from the vertical growth of reefs that tracked the rising sea ([Figure 6](#)). The initial reconstruction was based on drilling of offshore reefs around Barbados ([Fairbanks, 1989](#)). An extended set of analyses of the deeper corals from this site, combined with a model of continental deglaciation, indicated that the Last Glacial Maximum may have experienced this period of low sea level from as early as 26 000 years ago ([Peltier and Fairbanks, 2006](#)). The transgression is recorded at several

Figure 6 Record of postglacial sea-level rise from the peak of the glacial until the apparent cessation of ice melt around 6000 years ago (data from Barbados, Fairbanks, 1989; Huon Peninsula, Chappell and Polach, 1991; Tahiti, Montaggioni et al., 1997; and Mayotte, Comoro Islands, Camoin et al., 2004).

other sites. The latter part of this sea-level rise was determined simultaneously by drilling through the Holocene reef on the Huon Peninsula in New Guinea on the other side of the world, which showed a similar pattern of rise (Chappell and Polach, 1991). Subsequently, comparable long records of postglacial sea-level rise have been derived from Mayotte in the Comoros Islands and Tahiti in the Society Islands (Bard et al., 2010), with only a slightly shorter record from the Abrolhos Islands off the coast of western Australia (Eisenhauer et al., 1993). Independent support for the reconstruction of this pattern of sea-level rise comes from dating of muddy shoreline deposits such as mangrove wood and peat on the continental shelf off northwestern Australia and on the Sunda Shelf.

The curves derived from these disparate sites are remarkably similar and have been used in attempts to interpret phases of ice melt (meltwater pulses) and rapid sea-level rise (Figure 6). However, there is a limit to the rate at which reefs can accrete vertically. Although individual colonies of coral can grow rapidly, with massive corals averaging an extension of around 10 mm a^{-1} and branching corals up to 100 mm a^{-1} , the reef itself is a porous aggregation of coral containing calcareous algae and loose calcareous sediment, incompletely lithified into a structure and partially eroded by physical and biological erosion processes. Reefs rarely accrete vertically at rates of more than 10 mm a^{-1} , and in most cases at rates considerably less than this. Consequently, reefs have been unable to keep pace with the most rapid rates of sea-level rise that have been driven by pulses of meltwater, except on those coasts that are uplifting (Montaggioni, 2005). The peak of the last glaciation appears to have been terminated by rapid polar melting around 19 ka with little evidence that reefs in existence at that time were able to keep pace with the rising sea. Several phases of reef generation have been suggested separated by meltwater pulses. There is general acceptance of a rapid rise in sea level associated with meltwater pulse 1A (MWP-1A) around 14 ka when a rise of about 20 m occurred in less than 500 years, but there is less consensus in relation to subsequent periods of rapid sea-level

rise (Montaggioni and Braithwaite, 2009). One consequence of phases of rapid sea-level rise may be the drowning of reefs. Recently, extensive relict reefs have been described from water depths of around 30 m, both in the muddy waters of the southern Gulf of Carpentaria, Australia (Harris et al., 2008), and at the site of the southernmost Pacific reefs at Lord Howe Island (Woodroffe et al., 2010).

Holocene Sea-Level Variations

Whereas the early stages of postglacial sea-level rise appear to be generally similar at points around the tropics, or discrepancies can be modeled in terms of mantle viscosity, the pattern of mid- and late Holocene sea-level change varies geographically. As the rate of sea-level rise has slowed, regional disparities in the pattern of relative sea-level history have become increasingly apparent (Lambeck et al., 2010). Corals have played an important role in deciphering these sea-level changes.

A significant difference between the pattern of sea-level change in the Pacific and that in the West Indies was first recognized by Fairbridge (1961) who plotted radiocarbon ages for coral and other shoreline indicators from around the tropics onto one age–depth diagram. He interpreted the evidence to indicate a series of oscillations in sea level over the past few millennia, but the evidence for periods of sea level above its present level came primarily from Australia, whereas that for sea level remaining below present level came from Florida and the Caribbean. Since the 1970s, it has been increasingly accepted that the sea-level envelope which best describes the Pacific region reached a level close to present around 6000 years ago with evidence of a mid-Holocene sea-level highstand, whereas in the Atlantic region, sea level has been continuously rising up until present but at a decelerating rate (Adey, 1978).

It is now recognized that the earth's crust has undergone vertical movements in response to the loading of water in the ocean basins and across continental shelves. This is termed hydroisostasy. Rapid uplift of those areas that were covered by ice sheets has occurred, and intermediate field areas in what is termed the forebulge have undergone submergence as a result of compensation within the mantle (Lambeck et al., 2010). Those parts of the tropics that are in the far-field and therefore not influenced directly by the isostatic rebound that has accompanied the melting of the ice sheets, appear to have experienced a slight lowering of sea level over recent millennia. This process has been termed ocean siphoning; as the volume of water in the ocean is spread throughout the ocean basins that have increased slightly in size as a result of adjustments in the forebulge region (Mitrovica and Milne, 2002).

This is most clearly seen by the contrast in the elevation of sea-level evidence between the western Atlantic and the Indo-Pacific region. In the western Atlantic, there is no evidence for the sea level having been above its present level during the Holocene. Reefs contain fewer coral species in the West Indies than in the Pacific region. One species of staghorn coral, *Acropora palmata*, dominates the reef crest and grows most prolifically within the upper 5 m on the reef front. It has been widely used to reconstruct sea level because it is considered an indicator of shallow water (Lighty et al., 1982;

Toscano and Macintyre, 2003). Although the depth of living *A. palmata* has frequently been observed to be concentrated in this depth range, it is important to note that individual colonies of the coral are also present in deeper water. Use of material of this species recovered in cores has been further criticized because it is rarely possible to determine whether the dated material was actually in its growth position, and there are situations where fragments of this branching coral have been transported either to greater depths or onto land and deposited in storm ridges, implying that uncertainties of sea-level position could range over 10 m (Blanchon, 2005; Gischler, 2006). Figure 7 summarizes radiocarbon dating results, extending an earlier sea-level reconstruction for the West Indies and indicating sea-level rise at a decelerating rate up until present based on ages determined on *A. palmata*.

In contrast, there is widespread evidence from the Indo-Pacific region that the sea reached a level close to present at least 6000 years ago and that it has been slightly higher since then in much of the region. Figure 7 also shows radiocarbon dates from coral, and intertidal indicators such as mangrove sediments, from the northern Great Barrier Reef (Larcombe et al., 1995). The clearest evidence comes from regions where massive corals, particularly microatolls (described below), are found in their position of growth (Chappell, 1983). Whereas there are emergent reef limestones of Last Interglacial age on many islands in the Pacific, as described by Daly, it is also clear that some of the emergent reef limestones are Holocene in age and record a time of higher sea level.

Interpretation of the details of sea-level position requires a careful consideration of the evidence. On many island shorelines, there is a conglomerate of coral boulders, such as seen in Figure 8(a). However, storms are very effective at dislodging corals and transporting them, and depositing an accumulation of rubble. There has been an ongoing controversy as to the

extent to which radiocarbon dating of corals from within a boulder conglomerate provides evidence for a higher sea level. Some boulder conglomerates, containing disoriented fragments of coral, appear to be storm deposits (Figure 8(b)). Clearer evidence for the position of the sea can be discriminated where coral colonies can be unequivocally shown to be in the position in which they grew. For example, if corals and associated organisms, including *Tridacna* clams, occur in their position of growth and at an elevation above where they can now grow, the conglomerate can be inferred to have formed as part of a former reef that grew to a higher sea level (Figure 8(c)). Where fossil coral is found in its position of growth, there remains the need to establish the relationship to former sea level, often the coral is an indicative marker, indicating, as in the case of *A. palmata* that the sea surface was above the coral by anything up to about 5 m. In the Indo-Pacific, there are several corals that are considered to indicate water depths of less than 10 m; these include *A. robusta*, *A. humilis*, and *Pocillopora verrucosa* (Montaggioni and Braithwaite, 2009). Sometimes, fossil coral is found in growth position, but cannot be clearly related to a modern equivalent to verify the elevation to which it would have grown (Figure 8(d)). The vertical errors introduce uncertainties into the interpretation of former sea levels together with error terms associated with the dating techniques. Elsewhere, it may be possible to detect topographical features, such as the algal rim, or spur and groove features that characterize modern reef crests (e.g., the emergent Holocene limestone on Guam, Figure 9(a)), emerged above their modern equivalents. Encrusting vermetid gastropods, oysters, barnacles, and tubeworms have each been used as shallow-water indicators, as has the occurrence of cement types within reef deposits (Montaggioni and Braithwaite, 2009). One of the most convincing lines of evidence comes from regions where massive corals can be shown to have been constrained by former low tide levels.

Figure 7 Holocene sea level as indicated by radiocarbon dates on coral in the West Indies and northern Australia. An Atlantic sea-level curve (green line) is shown based on ages determined on *Acropora palmata* from Florida and the West Indies (after Toscano and Macintyre, 2003). Dates on corals from the Great Barrier Reef include fossil samples that grew in shallow water as well as indicators of intertidal elevations (after Larcombe et al., 1995), and imply a sea-level curve for northeastern Australia (purple line) that reached present sea level around 6000 years ago and has been higher than present for several millennia. It is important to note that there are vertical error terms (which are not shown) associated with each sample based on uncertainty as to the extent to which it indicates the elevation of former sea level, and age errors associated with the dating techniques (error terms are generally comparable to the size of the symbol).

Figure 8 Mid-to-late Holocene sea-level evidence at, and above, modern sea level from the Indo-Pacific region. (a) Many reef rims are characterized by a conglomerate, such as the coral conglomerate, that outcrops along the seaward shore of this reef island on the Cocos (Keeling) Islands in the eastern Indian Ocean; (b) a boulder conglomerate on Suvarrow Atoll in the northern Cook Islands in which the coral boulders are disoriented and appear to have been emplaced by storm activity; (c) a conglomerate immediately adjacent to that shown above, on Suvarrow, in which the corals are in growth position, and are accompanied by other biota (such as the *Tridacna* clam immediately behind the machete), which indicates a growing mid-Holocene reef at an elevation above that to which these organisms are presently able to grow; and (d) *in situ* branches of the blue octocoral *Helopora*, exposed on Addu Atoll in the Maldives, which indicate a sea level close to, and possibly slightly above, modern.

Figure 9 Microatolls: (a) the large flat-topped corals in the foreground are microatolls on Guam, they occur in an embayment into Holocene limestone (background) in which a spur and groove pattern (like that seen on the reef front in [Figures 2\(b\)](#) and [8\(a\)](#)) is preserved; (b) microatolls of a massive species of *Porites* within a field of branching *Acropora* on the reef flat in the Cocos (Keeling) Islands; (c) large specimens of *Porites* microatolls on Cocos from which it has been possible to extract a record for most of the twentieth century; and (d) uplifted corals from the southwest coast of Simeulue, off the western Sumatra, Indonesia. The upper surface of the coral has experienced a series of changes in water level related to the Indian Ocean dipole and coseismic uplift, culminating in the entire coral being lifted out of the water in the 2004 Aceh-Andaman earthquake (see [Meltzner et al., 2006](#); photo courtesy of Kerry Sieh).

Such large flat-topped corals are called microatolls and are described in the following section.

Not all corals within a reef, however, reflect the precise level of the sea. Most corals grow in shallow water and radiocarbon dates, even if they are on corals that are in their growth position, are directional, rather than indicative, of sea-level position (Montaggioni and Braithwaite, 2009). For example, it can be seen that most ages of fossil coral recorded from drilling studies on reefs in the Great Barrier Reef, and shown in Figure 7, fall below the curve interpreted to represent sea-level position.

Reef growth can adopt one of several strategies: keep up, catch up, or give up, depending on the reef's relationship to sea level and the rate and direction of sea-level change (Neumann and Macintyre, 1985). Reef growth involves the consolidation of reefal material into a structure; where rates of sea-level rise are too rapid, typically greater than 10 mm a^{-1} , the reef is drowned. At slightly slower rates of rise, the reef is displaced upward and landward, termed backstepping. As rates of sea-level rise decelerate, reef growth may catch up with sea level as appears to have happened on many atolls and on outer reefs on the Great Barrier Reef (Hopley, 1982). Where the rate of rise is similar to, or less than, the rate of reef growth, reefs have the potential to keep up with sea level, as has occurred with the reefs around much of the Caribbean. If the sea falls, as has happened across much of the Indo-Pacific region, then a reef may become emergent, with a relatively bare reef flat replacing formerly diverse coral communities, as shown by the emergent Holocene conglomerate platform that underlies many reef islands on the margins of atolls (Figure 8(a)).

Many Holocene reefs established over Pleistocene substrates as the rise in sea level slowed around 7000 years BP. Initial coring and dating of fringing reefs indicated similarity between reefs in Hanauma Bay in Oahu, Hawaii, and those at Galeta Point in Panama. In each case, the dating implied a reef growth history in which the reef grew up and then prograded out. The interpretation that this supported a similar decelerating sea-level curve in both locations went counter to evidence elsewhere in the Pacific that there had been a mid-Holocene sea level slightly above present. This discrepancy can be resolved if the Hawaiian reef is interpreted as a catch-up reef (Fletcher and Jones, 1996).

If sea level is stable, a reef that has reached sea level generally builds seaward, called progradation. The way in which it builds seaward varies in different settings, in some cases it may involve stepped build-out, and in others it may build uniformly (Kennedy and Woodroffe, 2002). Each of these sea-level and reef-growth scenarios can be illustrated by different reefs from around the world, illustrating the range of responses that Holocene reef morphology can show to variations in the rate of sea-level change. These growth strategies have been comprehensively described by Montaggioni (2005).

Microatolls and Interannual Variations in Sea Level

Individual colonies of massive coral can grow up to a level close to mean low tide and then continue to grow outward, forming flat-topped discoid corals, termed microatolls (Figure 9(a)). Microatolls initially termed miniature atolls, are living on the outer margin but are predominantly dead and

limited by water level on their upper surface (Figure 9(b)). Microatolls in their growth position are fixed biological sea-level indicators and can be useful indicators of the level that previously limited growth, with the larger specimens reaching several meters across and containing a growth record of tens to hundreds of years (Figure 9(c)).

Fossil microatolls have been used extensively to reconstruct Holocene sea-level variations on reef tops. For example, the significance of microatolls was recognized during the 1973 Royal Society expedition to the Great Barrier Reef, northeastern Australia, when it was realized that those found above sea level indicated a higher stand of the sea (Scoffin and Stoddart, 1978). Further study showed that sea level has been decreasing over the past 6000 years with respect to the inner Great Barrier Reef (Chappell, 1983). Much of the Indo-Pacific reef province has experienced relative sea levels in the mid- and late Holocene that have been slightly above present. Microatolls have sometimes been preserved at a height presently above that of their living counterparts on reef flats in the eastern Indian Ocean, Southeast Asia, northern Australia, and across much of the equatorial Pacific Ocean (Smithers and Woodroffe, 2000).

Typically, microatolls comprise a single colony of massive *Porites*, though several other genera can also adopt the microatoll form and grow to several meters in diameter. Microatolls grow upward until constrained by a water level close to mean low tide level, after which they continue lateral growth and become disk-shaped corals (Figure 10(a)), contrasting with dome-shaped colonies that are in water deep enough not to be constrained by sea level (Figure 10(b)). On coasts that experience seismic uplift, a coral previously not limited by sea level may be elevated above the water level, and the exposed upper surface will die, but with continued lateral growth at a lower elevation (Figure 10(c)). A spectacular example of this occurred in association with the 2004 Aceh-Andaman earthquake with uplift on the island of Simeulue, off the western coast of Sumatra (Meltzner et al., 2006; see Figure 9(d)). Where a microatoll, previously limited by water level, experiences an increase in the level of the sea, it can resume vertical growth and begin to overgrow the formerly dead upper surface (Figure 10(d)). Successive falls in water level result in exposure of the living rim, and a series of terracettes develop, recording the fall in water level (Figures 10(e)). Fluctuations of water level with a periodicity of several years are recorded on the upper surface of a microatoll as a series of concentric undulations or annuli (Figure 10(f)). This pattern has been described on microatolls from reef flats in the central Pacific tracking, but lagging behind, sea-level fluctuations that are linked to the atmospheric-oceanic El Niño phenomenon that is a major control on the ocean surface in the central Pacific Ocean (Woodroffe and McLean, 1990).

Banding within the coral provides insight into events in the life history of the coral. It can reveal times at which growth has been lowered by changes in the water surface. In areas where storms are experienced, overturning of the colony can occur during individual storms, or microatolls may have responded to the moating of water that could have occurred behind boulder ramparts formed as a result of storms. In these cases, their upper surface may record elevation of water level within impounded moats above that of regional sea level. Although in

Figure 10 A schematic illustration of the response of the upper surface of microatolls to changes of sea level or uplift of the land, with annual bands (laid down by the living tissue that is shown in red) within the coral skeleton recording the pattern of coral growth; (a) if sea level remains constant from year to year, a massive coral that has grown up to sea level continues to grow outward but with its upper surface constrained at water level; (b) if the coral does not reach water level, it adopts a domed growth form and is not constrained by water level; (c) if the coast undergoes uplift, then a coral previously not limited by sea level may be raised, and the exposed upper surface will die, but with continued lateral growth at a lower elevation (as in [Figure 9\(d\)](#)); (d) if the water level increases, a coral previously constrained by exposure at low tides can resume vertical growth and begin to overgrow the formerly dead upper surface; (e) if water level decreases, then the microatoll adopts a series of terraces; and (f) if there are fluctuations of water level with a periodicity of several years, then the upper surface of the microatoll consists of a series of concentric undulations – such a pattern can be seen on microatolls from reef flats in the central Pacific where El Niño results in interannual variations in sea level (based on [Woodroffe and McLean, 1990](#); [Lambeck et al., 2010](#)).

open-water situations microatolls can enable centimeter-scale reconstructions of former sea level, they are subject to misinterpretation if moating has occurred, and it is therefore important to assess the geomorphological setting within which these corals grew before using fossil specimens to draw conclusions about past sea levels. In addition to tracking sea level, emerged microatolls have been used to record uplift associated with earthquakes, as for example, along the Sumatran coast ([Sieh et al., 2008](#)), and may contain evidence of fluctuations in sea level at decadal to century time scales ([Yu et al., 2009](#)).

Microfossil-Based Reconstructions of Holocene Relative Sea-Level Change

W R Gehrels, University of Plymouth, Plymouth, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

Microfossils are an important tool for reconstruction of former sea levels, particularly in the Holocene. They are valuable sea-level indicators because their modern counterparts (i.e., microorganisms) are found in narrowly defined niches in the intertidal zone at specific height (or depth) ranges. The vertical living ranges of microorganisms such as Foraminifera, diatoms, and testate amoebae are controlled by limiting ecological parameters, including tidal flooding frequency, subaerial exposure, food availability, substrate composition, and salinity. These parameters play a role in interspecific competition, which results in vertical intertidal zonation of species assemblages (Figure 1). If the upper and lower limits of the vertical ranges of microorganisms are measured in the modern intertidal environment, it is possible to establish, from sediments containing the fossilized microorganisms, the elevation relative to sea level at which the sediments were deposited. This is an example of the principle of uniformitarianism: 'the present is the key to the past.'

There are many published Holocene sea-level studies in which microfossils are employed and this review does not attempt to be comprehensive. Some key references are included, while most illustrated examples in this review are chosen to highlight important concepts. The case studies are primarily from the coastal lowlands of western Europe and the salt marshes of eastern North America, but they are relevant for sea-level studies in comparable environments elsewhere.

This paper covers the application of Foraminifera, diatoms, testate amoebae, ostracods, and pollen in Holocene sea-level reconstructions. Testate amoebae and ostracods are less often used than Foraminifera and diatoms. However, testate amoebae in particular have the potential to deliver very precise Holocene sea-level information from salt-marsh sediments. Pollen analysis is commonly applied in sea-level studies, but pollen grains cannot be regarded as *in situ* sea-level indicators in the same sense as the other microfossil groups. Finally, the recent development of quantitative methods (i.e., the use of transfer functions) and the application of chronological techniques are briefly discussed. The transfer function methodology has become quite popular in the last decade and some advantages and pitfalls associated with the application of transfer functions are highlighted.

Microfossil Groups Used in Sea-Level Studies

Foraminifera

Foraminifera are single-celled organisms that are found in most marine environments, from the intertidal zone to the deep ocean. Shallow water Foraminifera are most useful for sea-level studies as their living range can be most easily related to sea level (Gehrels, 1994). Environmental conditions in the

intertidal zone produce intraspecific competition which results in a foraminiferal vertical zonation, often with narrow vertical ranges of distinct assemblages (Figure 1). The limiting factor that controls foraminiferal zonation is tolerance to subaerial exposure and only the hardest agglutinated Foraminifera (e.g., *Jadammina macrescens* in marshes in eastern North America) are capable of surviving in the uppermost intertidal zone. The potential of salt-marsh Foraminifera as sea-level indicators was first highlighted by Scott and Medioli (1978). Many studies have shown that intertidal foraminiferal zonation occurs in tidal marshes around the world, from high latitude salt marshes to low latitude mangrove environments (Gehrels, 2002). The most precise sea-level reconstructions based on Foraminifera have been produced in microtidal salt marshes on the eastern seaboard of North America (e.g., Gehrels et al., 2005; Kemp et al., 2009) and New Zealand (Gehrels et al., 2008). These reconstructions form a link between geological reconstructions and instrumental observations. They have revealed that ongoing sea-level rise represents a significant departure from slower rates of sea-level rise in the late Holocene. This sea-level acceleration started during the early twentieth century (Woodworth et al., 2009).

A distinct advantage of the use of Foraminifera as sea-level indicators is that in salt marshes abundances are generally high, while species diversity is low. The agglutinated species that are found in the upper parts of salt marshes are also well preserved in fossil sediments. Some agglutinated species have a universal occurrence, most notably *J. macrescens*, *Trochammina inflata*, and *Miliammina fusca*. Foraminifera are less useful in sediments from lower in the intertidal zone. Here calcareous genera are found (e.g., *Elphidium*, *Ammonia*, *Haynesina*, *Quinqueloculina*) and these are not well preserved in sediments due to dissolution, especially when sediments are organic in nature and acidic conditions are present. In deeper waters, the ecological controls that produce intertidal zonation become less influential and reduce the sea-level indicative value of Foraminifera.

Diatoms

Diatoms are single-celled algae that are found in almost every aquatic environment, both freshwater and marine. Diatom valves are built from silica and their preservation potential in fossil sediments is high. Like Foraminifera, they occupy limited environmental ranges in the modern intertidal zone (Nelson and Kashima, 1993). However, diatoms can tolerate both fresh water and marine conditions and their distributions are controlled by a number of environmental variables, including salinity, substrate type, temperature, and nutrient supply. Tidal conditions produce spatially variable conditions in the intertidal zone to which diatoms adapt. As a consequence, distinct diatom assemblages are found within narrow elevational ranges which makes them suitable as sea-level indicators.

Figure 1 An example of intertidal zonation displayed by Foraminifera in samples collected along the sloping surface of a salt marsh in eastern Maine (USA). Plant zones are also shown. Redrawn and modified from [Gehrels WR \(1994\)](#) Determining relative sea-level change from salt-marsh foraminifera and plant zones on the coast of Maine, U.S.A. *Journal of Coastal Research* 10: 990–1009.

Diatoms have been classified into salinity classes; where halophobes are freshwater diatoms, oligohalobes can tolerate low salinities up to 2‰, mesohalobes live in brackish water between salinities of 2 and 30‰, and polyhalobes are found in marine waters with salinities greater than 30‰ ([Palmer and Abbott, 1986](#)). However, ecological classifications of diatoms are still under debate. For example, more recent classification schemes have been extended to include other ecological parameters in addition to salinity ([Denys, 1991/2; Vos and de Wolf, 1993](#)). Changes in the relative abundances of these groups in sediment are indicative of changing marine

influence, often interpreted as transgressions or regressions. A classic diatom-based study of Holocene sea-level changes is the work by [Devoy \(1979\)](#). More recent studies increasingly use quantitative methods such as transfer functions (e.g., [Long et al., 2010; Sawai et al., 2004](#)).

Testate Amoebae

Testate amoebae are single-celled organisms that live in many terrestrial and aquatic habitats, including peat bogs, soils, lakes, and salt marshes. In the literature, they are also referred

Figure 2 Sea-level reconstructions for Chezzetcook (Nova Scotia, Canada), based on (a) salt-marsh testate amoebae and (b) salt-marsh Foraminifera. The reconstructions are compared with the tide-gauge record from nearby Halifax. Redrawn and modified from Charman DJ, Gehrels WR, Manning C, and Sharma C (2010) Reconstruction of recent sea-level change using testate amoebae. *Quaternary Research* 73: 208–291.

to as rhizopods, thecamoebians, and arcellaceans. Traditionally, testate amoebae have been considered to be exclusively freshwater organisms, although some taxa have occasionally been found in coastal marshes in studies that focused on Foraminifera (e.g., Scott et al., 1991). These testate amoebae were greater than 63 μm in size, as this size fraction is commonly used for foraminiferal analyses. However, studies in salt marshes in the United Kingdom and eastern North America have shown that testate amoebae smaller than 63 μm occur in very high abundances with much greater species diversities (Charman et al., 1998, 2002; Gehrels et al., 2006a; Roe et al., 2002). The preservation potential of testate amoebae is good in recent salt-marsh sediments, coastal raised bogs, and isolation basins, but in other coastal sediments (e.g., coastal reed swamps) preservation may be variable (Roe et al., 2002). An important environmental control on the distribution of testate amoebae is wetness, while salinity appears to limit their occurrence to the uppermost part of salt marshes (Charman et al., 2002). Testate amoebae are promising sea-level indicators. In the few places where they have been studied they occupy narrower intertidal niches than any other microfossil group (Charman et al., 1998; Gehrels et al., 2001, 2006a).

Charman et al. (2010) produced the first sea-level reconstructions based on testate amoebae found in short salt-marsh cores for two sites in eastern North America. The reconstructions are only 100 years long, but compare favorably with tide-gauge records and with reconstructions based on foraminiferal analyses (Figure 2). Importantly, assemblages of testate amoebae show strong similarities on both sides of the Atlantic Ocean, which enhances their applicability across large geographical areas. Important taxa with widespread occurrences in the upper salt marsh include *Tracheleuglypha dentata*, *Trinema lineare*, and *Euglypha rotunda*. *Centropyxis cassis*, *Centropyxis platystoma*, *Diffugia pristis*, and *Cyphoderia ampulla* are common in the high to middle salt marsh. In most salt marshes, testate amoebae are confined to the highest part of the marsh (and above) and are not found below the level of mean high spring tide, although occasionally they can occur as low as the mean high water level (Gehrels et al., 2006a).

Ostracods

Ostracods are small crustaceans, usually between 0.3 and 1.5 mm in size, that produce bivalved calcareous shells. They are found in both fresh and marine waters. Like Foraminifera,

marine ostracods occur in the entire marine realm, from intertidal areas to the deep ocean. Assemblages appear to be restricted to certain depth ranges. However, they are not considered to be precise sea-level indicators, mostly because the shells are easily transported (van Harten, 1986) and because many environmental parameters control their distributions, including salinity, water chemistry, temperature, and substrate (Frenzel and Boomer, 2005). Possible exceptions are assemblages that are found in intertidal environments. Here, species are generally restricted to low-marsh habitats and tidal channels and pools, and their use in sea-level applications is often in combination with Foraminifera. Frenzel and Boomer (2005) list many examples of the use of ostracods in Holocene sea-level studies.

Pollen

Pollen are the first microfossil group used in sea-level reconstructions (e.g., Godwin, 1940), albeit as a chronological tool. Pollen grains are transported, by wind or water, and reconstructing specific tidal levels from sediments based on pollen assemblages is therefore challenging. However, pollen assemblages are valuable in giving a general indication of the position of the sediments within the tidal frame. For example, many salt-marsh sediments contain a distinct pollen assemblage, including Chenopodoaceae and *Plantago maritima* and a range of other pollen types (Roe and van de Plassche, 2005), which allows differentiation from other environments. If the indicative meaning of a sea-level index point is based on pollen alone, the vertical uncertainties can be as large as the entire span of the upper intertidal zone, between mean high water and the highest astronomical tide level. Possible exceptions are mangrove environments, where other microfossils are often poorly preserved. Engelhart et al. (2007) found that pollen distributions in mangrove swamps in Indonesia appear to be zoned and well preserved in cores and could therefore be used to reconstruct sea-level changes.

Seminal pollen-based Holocene sea-level investigations were conducted by Tooley (1978) and Shennan (1982). Before the advent of radiocarbon dating, pollen analyses were used for providing a chronology based on widely recognized vegetation changes (Godwin, 1940). Pollen can be used to improve chronology if vegetational change provides a well preserved marker which has been dated in other locations. In coastal sediments in the United Kingdom, the Alder rise provides an early Holocene chronohorizon, while the Elm decline is a useful marker for middle Holocene sediments. For more recent coastal sediments, European settlement and forest clearance have provided some useful pollen markers along the eastern seaboard of North America (Gehrels et al., 2005; Kemp et al., 2009) and in New Zealand (Gehrels et al., 2008). In eastern North America, the expansion of ragweed (*Ambrosia*), dock (*Rumex*), and the decline of oak (*Quercus*) provide the most notable pollen signals. Figure 3 shows a pollen diagram from a salt marsh at Chezzetcook, Nova Scotia, eastern Canada. The arrival of settlers around AD 1780 left a distinct pollen marker which can be used to date the sediments (Gehrels et al., 2005). In some European coastal sites where pine plantations have been established, a recent rise in pine pollen provides a useful historical marker (Long et al., 1999).

In many sea-level studies from coastal lowlands, pollen analyses are often performed across boundaries between peat and minerogenic sediments (e.g., Shennan, 1982). Sea-level index points may be obtained from such boundaries if they are shown to represent a marine–terrestrial contact and if it can be demonstrated that the boundary represents an *in situ* stratigraphic contact. Pollen analyses are useful for the latter. For example, if the reconstructed vegetational succession contains a clear salt-marsh assemblage, sandwiched in between tidal flat and freshwater marsh deposits, the contact can be assumed to be nonerosional. Even if a stratigraphic contact from which a sea-level index point is derived is shown to be nonerosional, other factors, such as autocompaction, could still produce displacement and should be considered.

Methods of Microfossil-Based Sea-Level Reconstruction

Derivation of Sea-Level Index Points

A sea-level index point may be established when a fossil sea-level indicator is dated, its height is measured, and the height relative to sea level of its modern counterpart (the ‘indicative meaning’) is known. In theory therefore, any biota that is preserved in the fossil record and for which an indicative meaning and an age can be established can form the basis for a sea-level reconstruction. Microfossils are especially valuable for sea-level reconstructions in coastal lowlands where alternating beds of terrestrial and marine deposits provide evidence for transgressions and regressions. In these environments, sea-level index points are obtained from the contacts between peat and silt/clay beds, as these contacts are formed very high in the intertidal zone. The indicative meaning of these stratigraphic contacts is derived from the altitude of the boundary between reed beds and salt marsh in the modern environment which, in the English Fenland for example, is found very near the level of the mean high water of spring tides (Shennan, 1982). Microfossil analyses are useful to corroborate and further quantify the indicative meaning. The distribution of microorganisms in the modern environment forms the basis for achieving this (as discussed above; Gehrels et al., 2001).

A distinct disadvantage of using sea-level index points from peat-silt/clay contacts is that Holocene sequences of coastal deposits are subject to long-term consolidation. This process displaces the original position of sea-level index points downward and leads to overestimation of the rate of relative sea-level rise as sea-level index points from intercalated coastal deposits represent only limiting positions of sea level (Horton and Shennan, 2009). When sea-level index points are derived from a peat unit directly overlying a hard substrate (‘basal peat’), this problem is significantly reduced or even eliminated (Gehrels, 1999). Basal peat is formed at the leading edge of the Holocene transgression and its indicative meaning therefore is close to the highest astronomical tide. However, unless the upper limit of reed beds is known in the modern environment, sea-level index points derived from basal peat may still only represent limiting sea-level positions (i.e., sea level lies below the sea-level index point). This is an issue in the coastal plains of Belgium, the Netherlands, and Germany for example, where coastal fens have been reclaimed and the true indicative

Figure 3 Pollen diagram from a salt marsh in Chezzetcook, Nova Scotia, Canada, used to establish a sea-level history (Gehrels et al., 2005). Deforestation following European settlement around 1780 encouraged the spread of weeds (*Ambrosia*, *Rumex*) and produced a useful pollen marker which ties in with other chronological tools. The cultivation of hay has also increased the concentration of grass pollen (*Poaceae*). Redrawn and modified from Gehrels WR, Kirby JR, Prokoph A, et al. (2005) Onset of recent rapid sea-level rise in the western Atlantic Ocean. *Quaternary Science Reviews* 24: 2083–2100.

meaning of basal peat cannot be accurately determined. The situation is more advantageous if basal peat deposits are found that contain Foraminifera distinctive of salt-marsh environments (e.g., Gehrels et al., 2005) and if pristine environments from which the indicative meaning of microfossils can be established are abundantly present.

Transgressive and Regressive Sequences

Biostratigraphic changes in salt-marsh sediments can provide detailed continuous records of past sea-level changes (Thomas and Varekamp, 1991). Many sea-level records based on biostratigraphical methods have been derived from salt marshes along the Atlantic coast of North America, primarily North Carolina, Connecticut, Maine, and Nova Scotia. The provision of accommodation space by sea-level rise generates the potential for salt-marsh sediment to record sea-level changes, a concept that is well known in seismic stratigraphy over larger geological time scales. Transgressions in salt marshes are recorded when

sea-level rise outpaces accretion. Alternatively, regressions are recorded when accretion rates are faster than sea-level rise. The corollary of this is that, if accretion rates can be measured by dating methods, it is possible to calculate sea-level rise. If auto-compaction is significant, it is even possible to detect small sea-level falls, provided that autocompaction can be determined, for example, by dating basal peat (Gehrels, 1999). Both qualitative and quantitative methods have been used to detect biostratigraphical changes and relate these to changes in sea level.

Whatever the method of reconstruction, quantitative or qualitative, microfossils used in sea-level reconstruction should ideally be derived from sediments that have formed in the uppermost intertidal zone. Here, the relationship between elevation and species assemblages is most strongly defined. In deeper waters, the ecological parameter primarily responsible for the correlation between elevation and foraminiferal assemblages, that is, flooding duration, is no longer the limiting factor for species distribution and other environmental controls (e.g., nutrient levels, substrate type, water temperature,

wave energy, etc.) become more influential (Woodroffe, 2009). When a large number of environmental factors need to be taken into account, the risk that any of these has not remained constant over time increases and the uniformitarian assumptions of microfossil-based sea-level reconstructions may (unknowingly) be violated. Species diversity also tends to increase in deeper water, so that it is often not possible to define the lower limit of indicator species, a problem that makes it difficult to obtain accurate sea-level reconstructions. Other sedimentary factors that can complicate sea-level reconstructions from low intertidal (or even subtidal) sediments include erosion and rapid changes in sedimentation rate. Near the highest tide mark, changes in accommodation space are primarily produced by relative sea-level change, and the rate of sediment accretion approaches that of the rate of sea-level rise (Allen, 1990), although the process of autocompaction should also be considered.

Isolation Basins

In areas of isostatic uplift, sea-level changes can be reconstructed from microfossils present in basins that were isolated from the sea at some stage in their uplift history. The isolation process produces distinct stratigraphic evidence preserved in contemporary lakes or raised bogs, with marine deposits buried beneath freshwater lake deposits or terrestrial peat. The isolation event is marked in the stratigraphy by the contact between the marine and terrestrial deposits. The dating of the contact provides the age of isolation, whereas the height of the sill that separates the basin from the sea represents the height of the former position of sea level during isolation. In some isolation basins, marine deposits can be found above freshwater sediments, which indicates that sea water reentered the basin when the rate of uplift fell behind the rate of sea-level rise. From each of the stratigraphic contacts between marine and freshwater sediments, it is possible to obtain a sea-level index point (Shennan et al., 1994).

Lloyd (2000) worked in an isolation basin at Loch nan Corr in northwest Scotland along a macrotidal coastline. While in many sea-level studies, a large tidal range poses problems, here it creates an opportunity to recognize various stages of transgressions and regressions (Figure 4). The evidence is obtained from analyses of Foraminifera and testate amoebae. The rate of uplift in this area is relatively slow and it took about 7000 years for the isolation process to be completed. Lloyd (2000) was able to obtain five sea-level index points to reconstruct the relative sea-level changes at Loch nan Corr.

Seismic Vertical Motion

Uplift and subsidence events produced by earthquakes occur suddenly and the changes in microfossils are abrupt and often dramatic. The changes are usually also visible in the lithostratigraphy, with soils or marsh deposits directly overlain by tidal flat deposits or vice versa. Foraminifera and diatoms have been used to quantify the amount of vertical displacement produced by earthquakes, especially along the Pacific coast of North America (e.g., Hemphill-Haley, 1995) and in New Zealand (e.g., Hayward et al., 2007). In northeastern Japan, Sawai

Figure 4 Changes in Foraminifera indicate the slow withdrawal of the sea from an isolation basin in northwest Scotland over the last 9000 years. The isolation process had reached completion when freshwater testate amoebae started living in the basin. From the microfossil changes, six radiocarbon dates and the height of the sill that separates the basin from the sea, a sea-level history has been reconstructed. Redrawn and modified from Lloyd J (2000) Combined foraminiferal and thecamoebian environmental reconstruction from an isolation basin in NW Scotland: Implications for sea-level studies. *Journal of Foraminiferal Research* 30: 294–305.

Figure 5 Diatoms in a coastal sequence in northeastern Japan have recorded preseismic subsidence and postseismic uplift of almost a meter. The seismic event produced a tsunami deposit. Redrawn and modified from Sawai Y, Satake K, Kamataki T, et al. (2004) Transient uplift after a 17th-century earthquake along the Kuril subduction zone. *Science* 306: 1918–1920.

et al. (2004) used diatom evidence to quantify preseismic and postseismic vertical land movements caused by large earthquakes (Figure 5).

Transfer Functions

Relative sea-level changes can be reconstructed both qualitatively and quantitatively. Both approaches involve the determination of the indicative meaning of sea-level indicators in the modern environment. With qualitative methods, the water-level relationship is determined in the modern environment by surveying. The observed modern ranges of indicators are then applied to the fossil counterparts by simply assuming that the surveyed range also applies to the fossil assemblage. With quantitative techniques, the heights of sea-level indicator microfossils are also surveyed, but their indicative meaning is established by statistical methods. The regression models used for this purpose can be linear or unimodal, depending on the distribution of the species along the height gradient, and they provide quantitative information on the ranges and optima of modern microfossil taxa with their errors. These values are then used to calculate the height of deposition of a given stratigraphic level based on the microfossil content of that horizon. The calculation of errors is an important feature of this technique and makes it arguably a more objective method than qualitative approaches.

The term ‘transfer function’ is used to describe the set of regression equations that is developed from modern relationships between modern environmental parameters and relative abundances of microorganisms. After its formulation, the

transfer function is applied to fossil sediments, usually in a core, to reconstruct past changes of the same environmental parameter(s) from the changes in microfossil assemblages. Transfer functions have been used in paleoecological studies since the early 1970s (Imbrie and Kipp, 1971), but in sea-level reconstruction, this quantitative approach was not applied until much later (Gehrels, 2000; Guilbault et al., 1995; Horton et al., 1999). These studies were based on Foraminifera, but transfer functions are also used in sea-level reconstructions based on diatoms (e.g., Sawai et al., 2004) and testate amoebae (e.g., Charman et al., 2010).

An important validation of transfer functions is possible when sea-level reconstructions derived from transfer functions can be directly compared with sea-level observations. Gehrels (2000) produced such a comparison for two salt marshes in Maine (Figure 6). One core is from a middle intertidal setting and includes high abundances of *M. fusca*, a middle-to-low marsh foraminifer which can also be found on tidal flats. The other core is from the high marsh and includes mostly typical high marsh Foraminifera, such as *J. macrescens*, *Balticamina pseudomacrescens*, and *Tiphrotrocha comprimata*. The resulting sea-level reconstructions based on a weighted-averaging transfer function reproduce the trends observed in the tide-gauge records well, but the variability in the reconstruction of middle marsh sediments is much greater than that for the high marsh core.

Recent studies have indicated that the application of transfer functions can lead to spurious results, especially when analogs for fossil assemblages are not present in the training set (Woodroffe, 2009). In these cases, it is preferable to combine the use of statistics with qualitative methods based on a visual assessment of the training sets (Long et al., 2010).

Figure 6 Two recent sea-level reconstructions from (a) high salt-marsh deposits and (b) low salt-marsh deposits from Maine (USA). The high salt-marsh reconstruction from Machiasport is more accurate and less 'noisy,' as is shown by a comparison with a nearby tide-gauge record. Redrawn and modified from [Gehrels WR \(2000\)](#) Using foraminiferal transfer functions to produce high-resolution sea-level records from salt-marsh deposits, Maine, USA. *The Holocene* 10: 367–376.

Chronologies

Radiocarbon dating is the traditional method to provide chronologies for microfossil-based Holocene sea-level reconstructions when sediments are older than ~300 years. Preferred materials for dating are plant fragments, horizontally embedded within the sediment sequence (e.g., [Gehrels et al., 2005](#)) or subsurface rhizomes and stalks with a well-defined relationship to the surface (e.g., van de Plassche, 2000). Macrofossils provide greater chronological precision than bulk dating of

organic sediments ([Törnqvist et al., 1998](#)). In rare cases, optically stimulated luminescence (OSL) dating has been applied, for example, in Denmark ([Szkornik et al., 2008](#)).

More recent sea-level reconstructions commonly rely on the ^{210}Pb method (e.g., [Gehrels, 2000](#)). A reliable ^{210}Pb chronology, however, is dependent on the choice of sedimentation model and ^{137}Cs measurements are therefore helpful to establish additional markers which can be used for calibration. In addition to ^{137}Cs , stable lead isotopic ratios can be used to validate the chosen ^{210}Pb model through detection of important changes in

the isotopic composition of atmospheric Pb produced by industrialization and car emissions (Gehrels et al., 2006b, 2008). More advanced radiocarbon methods, including high-precision and 'bomb-spike' dating, also offer potential for dating recent sediments (Marshall et al., 2007).

Conclusions

Microfossil groups that are used as indicators of sea-level changes in Holocene deposits include Foraminifera, diatoms, testate amoebae, and ostracods. Pollen are useful as indicators of coastal vegetation changes. Along isostatically subsiding coastlines, the most precise and accurate sea-level information is derived from microfossils that occur in the highest part of the intertidal zone. Microfossil analyses provide the indicative meaning for Holocene sea-level index points derived from transgressive and regressive stratigraphic contacts in buried coastal deposits. Detailed examinations of continuous biostratigraphic sequences may provide (sub)centennial scale fluctuations of relative sea-level change. This approach has been successfully used in salt marshes. The application of transfer functions has enabled the quantification of errors associated with sea-level reconstructions. Along isostatically uplifting coasts, microfossils preserved in isolation basins record changes in relative sea level. Abrupt relative sea-level changes produced by earthquakes can also be quantified by microfossils. Chronologies for microfossil-based sea-level reconstructions are based on a variety of methods, including ^{14}C , OSL, ^{210}Pb , ^{137}Cs , pollen, and geochemical markers.

Eustatic Sea-Level Changes – Glacial–Interglacial Cycles

Introduction

Changes in relative sea-level result from the interplay of several processes operating at different rates and over contrasting spatial and temporal scales. During the Quaternary, the dominant mechanism responsible for sea-level changes has been the progressive buildup and decay of continental-scale ice sheets in response to Milankovitch forcing insolation changes. Relative changes in sea level, expressed at the global scale, were termed eustatic by [Suess \(1906\)](#), and evidence for such changes can be seen along many of the world's coastlines, apart from regions where former evidence has been largely destroyed by erosional processes (e.g., parts of northern Europe where late Pleistocene glaciation has eroded much of the pre-Holocene coastal stratigraphical record or regions that have experienced significant erosion at times of glacial low sea level). Fluctuations in global ice volume account for the majority of relative sea-level change in the Quaternary and accordingly are termed glacioeustatic in nature.

During the Last Glacial Maximum (LGM), excluding Antarctica, an additional 13% of the Earth's surface was covered in ice, corresponding with an ice volume of approximately $52.5 \times 10^6 \text{ km}^3$ ([Yokoyama et al., 2001](#)). Maximum ice sheet thickness exceeded 2500 m over extensive areas of Fennoscandia, particularly the Gulf of Bothnia in northern Europe, and over 3000 m for the Laurentide Ice Sheet centered over Hudson Bay on the North American continent ([Boulton et al., 1985](#); [Lowe and Walker, 1997](#)).

Studies of sedimentary successions on continental shelves and shallow marine platforms such as southeastern Australia (New South Wales), Bonaparte Gulf, northwestern Australia, and Barbados have indicated a maximum sea-level lowering of between <130 and 121 m during the LGM some 20–22 ka ago ([Bard et al., 1990](#); [Ferland et al., 1995](#); [Lambeck and Chappell, 2001](#); [Yokoyama et al., 2001](#)). These findings are consistent with independent observations such as modeling global ice volumes and oxygen isotope evidence that place ice-equivalent sea level between 135 and 120 m below present sea level during the LGM ([Clark and Mix, 2002](#)). These estimates for full glacial sea-level lowering are less than originally predicted on the basis of model calculations of ocean volume accommodation space and estimates of water locked up in continental ice, which had placed LGM ice-equivalent sea level at approximately –154 m ([Williams et al., 1998](#)).

A thorough understanding of the response of the ocean floor and continental shelves to differential water loads is central to accurately quantifying the magnitude of eustatic sea-level change from glacial maxima to interglacials and therefore accounting for the difference between observed and predicted values for eustatic (ice-equivalent) sea level. Larger water volumes will have a greater loading effect on the ocean floors and continental shelves and accordingly will reduce the magnitude of relative sea-level rise as observed along coastlines

during interglacials. In a similar manner, crustal isostatic loading will respond differently to ice or water (liquid state). For every 100 m of ice loading, the continental crust is isostatically depressed by 27 m and it is depressed up to 30 m in response to loading by water due to its higher density.

The geological record reveals major contrasts in the rate of changes in ice volume with time and, as a corollary, glacioeustatic sea-level changes. The last glacial cycle, for example, was characterized by an overall gradual increase in ice volume following the last interglacial maximum over a period of approximately 96 ka (i.e., from the end of the last interglacial maximum ca. 116 to the LGM at 20 ka: [Figure 1](#)). The broad pattern of sea-level changes accompanying the development of the continental ice sheets during the last glacial cycle conforms to a saw-tooth pattern of sequential decline. The record reveals a progressive increase in ice volume punctuated with periodic rises in sea level during interstadials. However, during deglaciation following the LGM, sea-level rise was rapid and occasionally occurred at rates approximately 20 times faster than the rate of sea-level lowering during ice sheet development.

Sea-level curves that depict major changes in the height of the sea surface with respect to the land (i.e., relative sea levels) since the start of the late Pleistocene (ca. 128 ka) are derived from restricted regions. Although such records are site-specific and involve assumptions of a 6 m above present sea-level (APSL) datum for the last interglacial maximum (128 ka) sea surface and a constant rate of uplift since that time, they do show broad similarities globally ([Aharon, 1984](#); [Steinen et al., 1973](#); [Figure 1](#)). Thus, the sea-level curves derived from the emergent coral terraces of Barbados and Huon Peninsula, Papua New Guinea, show a striking similarity in the long-term general trend of sea level, reflecting the dominantly glacioeustatic cause. Local variations in paleo sea level are due to glacio–hydro-isostatic feedback effects on continental shelves of contrasting widths and, in the near field of former ice sheets, progressive mantle adjustments in response to fluctuating ice volumes. These trends are further complicated by steric effects on sea level (e.g., changes in water volume accompanying changes in surface water temperatures).

The Nature of Glacial–Interglacial Cycles

The broad pattern of relative sea-level changes during glacial–interglacial cycles of the past 1 Ma has been inferred in part from evidence for relative sea-level changes of the last glacial cycle (approximately the past 128 ka). This has involved uniformitarian reasoning that similar patterns of eustatic sea-level changes are evident in the longer geological record and is predicated by the hypothesis that long-term insolation changes are primarily responsible for ice volume changes (Milankovitch hypothesis). The validity of this reasoning rests heavily on the spectral signatures of oxygen isotope ($\delta^{18}\text{O}$) data from deep-sea and ice

Figure 1 Glacioeustatic sea-level curves for the last glacial cycle (late Pleistocene and Holocene) from Barbados (Steinen et al., 1973) and Huon Peninsula, Papua New Guinea (Aharon, 1984) illustrating the general pattern of sequential decline of sea level with time until the attainment of lowest sea levels during the Last Glacial Maximum (20–22 ka ago). The marine oxygen isotope stages of the last glacial cycle are indicated on the Barbados sea-level record. The records of the last glacial cycle are correlated with the benthic oxygen isotope record from equatorial Atlantic core ODP-607 (Raymo, 1992). Core ODP-607 spans the past 3.2 Ma. Solid horizontal lines indicate the $\delta^{18}\text{O}$ values for the Holocene (top line), substage 5c (middle line), and the stage 2/1 boundary (bottom line) as determined at this core site. Oxygen Isotope Stages (OIS) are indicated for some of the glacials (even numbers) and interglacials (odd numbers). The $\delta^{18}\text{O}$ values for OIS 5 (actually substage 5e), 9, 11, 31, 37, and 43, as determined at this core site, imply sea levels higher than present for these interglacials. The 100 ka cycles appear to commence at about 1 Ma ago (the middle Pleistocene transition) and the previous 2 Ma are dominated by the 40 ka cycles characterized by lower amplitude sea-level variations. The progressive draw-down of sea level in response to the formation of the Antarctic Ice Sheet is evident in the basal 600 ka record in this core.

cores which for the past seven glacial cycles show a very generalized similarity in the timing and amplitude of isotopic changes, and as a corollary, eustatic sea-level changes (Masson-Delmotte et al., 2010; Raymo, 1992). Because a 0.1‰ change in $\delta^{18}\text{O}$ is equivalent to a 10-m change in eustatic sea level, the magnitude of eustatic sea-level fluctuations may be indirectly inferred from the isotopic record of deep-sea cores, with due allowance for local variations in isotopic signals in response to

water temperatures and salinity. The timing of these changes may be inferred from average rates of sedimentation in deep-sea cores, which are generally calibrated either by radiocarbon dating toward the top of cores for the past 50 ka, U-series for the past 400 ka, or by recognition of the Brunhes–Matuyama geomagnetic polarity reversal at 780 ka for longer records (i.e., the change from normal to reversed magnetic polarity, which generally represents the first magnetic reversal to be observed down

from the top of cores). The isotope records have adopted a numbering scheme such that odd numbers refer to warmer intervals, such as interglacials and interstadials, whereas even numbers refer to glacials or stadials (Figure 1).

The most detailed pattern of relative sea-level changes has been derived for the last glacial cycle, which commenced at the end of the last interglacial maximum (marine oxygen isotope substage 5e) approximately 116 ka ago. Whereas knowledge of paleo sea levels for earlier glacial cycles is more reliant on indirect inferences from isotopic records (particularly before interglacial stages 7 at 220 ka or 9 at 322 ka), sea levels of the last glacial cycle have been directly determined from geomorphological and stratigraphical evidence from many emergent coastlines, particularly those located near subduction complexes. Radiocarbon and U-series dating of emergent fossil coral reef successions indicating former sea levels, correlated with inferences derived from the marine oxygen isotope records of ice volume change (and as a corollary, eustatic sea-level changes), have provided the basic framework for understanding the pattern of eustatic sea-level changes for the past 140 ka. Initially, the evidence for interstadial sea-level highstands of Stage 5 (substages 5c and 5a) and Stage 3, as seen in Barbados and Papua New Guinea, were correlated with isotopically inferred sea levels for these intervals (Shackleton and Opdyke, 1973). Numerous subsequent studies have corroborated the correlations of isotopic events with discrete eustatic high stands from many localities throughout the world.

The last glacial cycle commenced with an abrupt fall in sea level at the end of the last interglacial maximum (OIS substage 5e) at approximately 116 ka. The last interglacial maximum occurred from approximately 128 to 116 ka ago. Although field evidence suggests a range of values, sea level was at least 2 m APSL during this period, and estimates from Indian and Pacific Ocean islands suggest values between 2 and 9 m APSL (Hearty et al., 2007). Isotopic records suggest that sea level fell by as much as 20 m within a few thousand years at the end of the last interglacial maximum (Shackleton, 1987).

OIS 5 has five subdivisions. Following the last interglacial maximum, eustatic sea levels fell during the stadial of substage 5d and rose during interstadial 5c to -10 m at approximately 105 ka. This was followed by a subsequent fall in sea level during the stadial of 5b and rose again during the subsequent interstadial 5a at 82 ka (-15 to -20 m). Interstadial 5a was followed by the stadial of Stage 4, which in turn was followed by the interstadial of Stage 3.

Eustatic sea levels of Stage 3 have been subject to several interpretations. Early reports of radiocarbon ages suggested that sea levels during interstadial Stage 3 were close to present approximately 30–40 ka ago. Subsequent studies, however, revealed that the radiocarbon ages underestimated the true age of the fossils and that the deposits correlated with the last interglacial maximum as supported by U-series dating and paleoclimatological reconstructions (Chappell, 1982; Thom, 1973). The radiocarbon ages represented minimum, apparent ages reflecting between 1% and 2% contamination by modern ^{14}C that could not be removed during sample pretreatment. More recent investigations have shown that sea levels during Stage 3 (70–30 ka) were 20–40 m lower than originally determined based on a reinterpretation of the Huon Peninsula emergent coral reef record (Chappell et al., 1996). Interstadial

Stage 3 sea levels for the interval 70–30 ka range between -90 and -45 m, with a modal class of about -65 m. The reinterpreted paleo sea levels for Stage 3 from the Huon Peninsula (Chappell et al., 1996) were previously anticipated based on inferences from marine isotope records based on studies of fossil foraminifer (Shackleton, 1987) and have been corroborated from other far-field environments such as the Lacedpede Shelf in southern Australia (Hill et al., 2009).

The LGM (Stage 2) followed Stage 3 and represents the period of lowest sea level during the last glacial cycle. Although isotopic records bracket the LGM between about 11 and 29 ka, sea level maintained its lowest level between 30 and 19 ka (Lambeck et al., 2002). At this time, continental areas were significantly larger, resulting from the lower sea levels. Australia had a land area up to 25% greater than present and land bridges extended between the mainland and Tasmania as well as Papua New Guinea. Similarly, the Sunda Shelf provided a land connection between Borneo, Java, Sumatra, Malaya, and Vietnam, and Beringia represented a major land bridge between the North American and Asian continents.

The inferred general pattern of eustatic sea-level changes for the past seven glacial cycles is based on the similarity of the spectral signature of oxygen isotope records of earlier glacial cycles with the last glacial cycle, as first noted by Emiliani (1955). In the most general sense, as seen in the benthic oxygen isotope record of equatorial Atlantic core ODP-607 (Raymo, 1992), the past six glacial cycles all show a broadly similar asymmetric pattern reflecting rapid deglaciation and sea-level rise heralding the onset of interglacials, and the slower formation of ice sheets over the course of each glacial cycle. The glacial cycles preceding the most recent cycle all show interglacials as the times of highest sea level. Core ODP-607 suggests that isotope Stages 5e, 9, and 11 were warmer than the current Holocene interglacial and, as a corollary, experienced higher sea levels. Based on a comparison of several deep-sea cores, Shackleton (1987) concluded that continental glaciation is likely to have been greater in Stage 6 than in Stage 2, and that Stages 12 and 16 experienced more extensive ice cover and lower sea levels, a finding corroborated by the northern Red Sea oxygen isotope record which revealed that during OIS 12 global ice volume was approximately 15% greater than during the LGM (Rohling et al., 1998). A similar pattern of glacial and interglacial intensities is evident in the EPICA Dome C ice core record from Antarctica (Masson-Delmotte et al., 2010).

Approximately 1.2 Ma ago, a notable change is evident in marine oxygen isotope records (the middle Pleistocene transition) from the 41-ka dominated cycles of the early Pleistocene to the 100-ka duration glacial cycles that have characterized middle and late Pleistocene time (Raymo et al., 2006; Shackleton et al., 1990). This trend is also evident in ODP-607, where the amplitude in isotopic signal ($\delta^{18}\text{O}$) in the higher frequency 41 ka cycles is less pronounced than in the 100-ka dominated cycles. The 3.2 Ma record of ODP-607 also shows an apparent overall increase in ice volume between 3.2 and 2.6 Ma that heralded the onset of the Quaternary. In the longer geological record, a series of plate tectonic reorganizations contributed to the establishment of the Antarctic Ice Sheet accounting for this draw-down in eustatic sea level and include the closure of the Isthmus of Panama (ca. 3 Ma), the opening of the Drake Passage between the Antarctic Peninsula

and the southern tip of South America (ca. 23 Ma), and the collision of Africa with Europe in the late Miocene.

High-Frequency Sea-Level Changes and Heinrich Events in the Last Glacial Cycle

Studies of ice cores have provided a greater opportunity to resolve short-term climate changes than previously possible with deep-sea sediments. Greenland ice cores reveal numerous abrupt changes in $\delta^{18}\text{O}$ during the last glacial cycle, termed Dansgaard–Oeschger cycles. Dansgaard–Oeschger cycles typically have a duration of approximately 1460 years, of which the last 600 years is represented by a distinct cold phase that ends abruptly with a pronounced change to warmer conditions. North Atlantic deep-sea sediments reveal the presence of discrete layers of lithic fragments (e.g., angular fragments of quartz, limestone, and dolomite) termed ice-rafted debris (IRD), which appears to precede the warming phases of Dansgaard–Oeschger events. Dansgaard–Oeschger cycles have been grouped into Bond Cycles in North Atlantic deep-sea sediments, and they end with well-defined IRD horizons termed Heinrich events. The IRD is associated with mobile sea ice in the North Atlantic Ocean. Oxygen isotope evidence from ice cores suggests that Dansgaard–Oeschger events may potentially be accompanied by sea-level changes of several tens of meters because their isotopic signature is about 50–75% that of the amplitude of glacial–interglacial changes in $\delta^{18}\text{O}$.

The Huon Peninsula, Papua New Guinea, reveals evidence for short-term sea-level changes associated with Heinrich events. The coral reef terraces reveal six discrete phases of sea-level rise and subsequent fall between 9 and 20 m lasting approximately 1–2 ka for the period 65–30 ka ago (Chappell, 2002). These results imply potential multiple sources for the meltwater returned to the world ocean associated with these oscillations, because the complete melting of the Greenland Ice Sheet would raise sea level by only approximately 5 m. Stratigraphic analyses of the geometry of the reef terraces at Huon Peninsula and their dating by U-series reveal that the rates of sea-level rise associated with these interstadials did not exceed the more rapid phases of deglacial sea-level rise following the LGM.

Evidence for Glacioeustatic Sea-Level Changes Prior to the LGM

Evidence for former sea-level highstands is apparent in regions that have been subjected to tectonic uplift, particularly near subduction zones (Chappell, 1974; Pirazzoli et al., 1993), and in regions characterized by a relatively high degree of tectonic stability (e.g., intraplate settings such as Australia) (Murray-Wallace, 2002). In general, the most detailed records of former eustatic sea level have been derived from flights of uplifted coral reef terraces, where there is a clear physical separation of highstand events due to high rates of tectonic uplift, as well as the opportunity to confidently define paleo sea level from well-dated coral reef facies. Uplifted settings also record interstadial events when sea level was significantly lower than present but higher than glacial lowstands (e.g., interstadial OIS 3 at –65 m). Uplifted regions also tend to provide a more

complete record of eustatic sea-level changes than tectonically more stable areas which tend to preserve evidence only for the highest points of glacial cycles (i.e., interglacial sea-level highstands).

In emergent reef settings, interglacial highstand records may extend back 1 Ma (Pirazzoli et al., 1993). In general, however, eustatic sea-level records typically extend back to only about 400 ka, a function of geological preservation rather than a coincidence with the practical limit of U-series dating. Along tectonically more stable coastlines, there is a greater likelihood that stratigraphical evidence for former sea levels has been destroyed by erosion, particularly by fluvial processes during sea-level lowstands. Accordingly, coastlines characterized by higher levels of tectonic stability tend to preserve evidence for the past two glacial cycles, particularly the penultimate (OIS 7 at 220 ka) and last interglacial (OIS substage 5e at 128 ka) records, as well as the current and ongoing Holocene interglacial.

Classical Field Localities for the Reconstruction of Paleo Sea Levels

Many areas of the world's coastlines have been examined for evidence of former eustatic sea levels. The Huon Peninsula in Papua New Guinea and Barbados represent examples of subduction settings in which the interaction of high rates of tectonic uplift (ranging from 3.5 to 0.27 m ka^{–1}, respectively) and relative sea-level changes have resulted in well-defined marine terraces. Coral reef terraces have formed on the Huon Peninsula and Barbados and are represented by *in situ* reef facies and associated lagoonal deposits. The marine terraces in these settings each generally record the culmination of a marine transgression, a highstand, and the onset of a fall in relative sea level at the end of a highstand (forced regression).

In contrast, the Coorong Coastal Plain in southern South Australia is represented by temperate carbonate coastal barriers deposited in response to high wave energy on a low-gradient coastal plain subject to slow rates of uplift (0.07 m ka^{–1}). The latter is an example of trailing edge, a passive continental margin, and is significant for its particularly long record of Quaternary sea-level changes.

Huon Peninsula, Papua New Guinea

Arguably the most detailed picture of eustatic sea-level changes for the later Quaternary has been derived from the Huon Peninsula, Papua New Guinea (Chappell, 1974; Chappell et al., 1996). The Huon Peninsula preserves evidence for numerous interglacial and interstadial sea-level highstands in the form of emergent fringing reef complexes (Figure 2). The peninsula is situated in a particularly complex geotectonic setting on the South Bismark Sea Plate, a microplate between the northward trending Indo-Australian Plate and the southwesterly trending Pacific Plate in a zone of one of the fastest rates of plate convergence in the world (ca. 120 km Ma^{–1}). Uplift of the Huon Peninsula is due to its proximity to the subduction zone at the New Britain Trench and a series of thrust complexes to the southwest of the peninsula.

The marine terraces extend up to 1000 m APSL. Uplift appears to be coseismic in nature, with the rates of long-term uplift being higher closer to the subduction zone. Uplift rates

Figure 2 Oblique aerial photograph of the Huon Peninsula, Papua New Guinea showing the well-defined uplifted coral reef terraces. Each terrace has developed during a sea-level highstand during either an interglacial or interstadial. From Figure 15.1, Ollier CD, *Tectonics and Landforms*. Copyright © 1981 Longman, London.

Figure 3 A relict sea cliff, visor, and notch, Barbados. The relict sea cliff, locally termed the Second High Cliff, has a northerly trend on the western side of Barbados and represents the seaward margin of a former reef terrace of one of the island's oldest reefs. A last interglacial highstand (minimum age) gave rise to the visor and notch and modified the coastal cliff formed in middle Pleistocene coralline limestone. Photograph by Murray-Wallace.

averaged since the last interglacial (128 ka) range from 0.7 m ka^{-1} on the northwestern sector of the peninsula to 3.5 m ka^{-1} closest to the subduction zone. A detailed record of eustatic highstand events is preserved for the past 300 ka with the principal interstadials and interglacial maxima represented. The individual reef terraces record evidence for rising sea level and the ensuing highstand, the latter in the form of regressive lithofacies associations. The Huon Peninsula sea-level record also reveals evidence for short-term sea-level events associated with Heinrich events as previously discussed. Accordingly, the region represents one of the world's most detailed archives of eustatic change in the later Quaternary.

Barbados

Barbados is located in the Caribbean Sea approximately 150 km east of the Lesser Antilles. Covering an area of 430 km^2 , the island is a fore-arc ridge, representing the subaerial component of an accretionary prism resulting from the North American

Plate being subducted beneath the Caribbean Plate (Schellmann and Radtke, 2004). Mud diapirism since late Eocene time is responsible for ridge formation. Approximately 85% of the island is covered by Pleistocene coralline limestone that ranges between 15 and 130 m in thickness and extend up to 300 m APSL. The coralline limestone formed from a series of fringing reefs that have developed as the island progressively emerged during the Pleistocene ($0.23\text{--}0.38 \text{ m ka}^{-1}$). The northern part of the island has a glacioeustatic sea-level record extending beyond 600 ka, whereas the island's southern sector has an emergence record younger than 400 ka (Schellmann and Radtke, 2004). Two prominent, high coastal cliffs extend around the island, with the First High Cliff trending east–west on the southern part of the island and the Second High Cliff trending north–south on the northwestern part of the island (Figure 3). The prominent cliffs represent the boundaries between individual reef complexes and have been modified by subsequent sea-level changes and subaerial processes.

The Barbados relative sea-level record is particularly significant because its correlation with the Huon Peninsula record compellingly demonstrates that the changes in sea level are predominantly an expression of global processes (Steinen *et al.*, 1973). A detailed record of glacioeustatic sea-level highstands for the past four glacial cycles has been derived from the Barbados reef complexes based on U-series and electron spin resonance dating (Schellmann and Radtke, 2004). The record indicates, for example, that sub-Milankovitch sea-level oscillations were responsible for the formation of three morphologically distinct reef terraces in oxygen isotope substage 5e with uplift-corrected sea levels of approximately 0 m (i.e., present sea level) between 132 and 128 ka, –2 m at 128 ka, and –13 m between 120 and 118 ka (Schellmann and Radtke, 2004).

Coorong Coastal Plain, South Australia

The Coorong Coastal Plain in southern South Australia represents globally one of the longest Pleistocene highstand records for interglacial sea levels set on a passive, trailing-edge continental margin (Murray-Wallace *et al.*, 1998; Figure 4). Covering an area of some 24 000 km², the coastal plain is a broad, flat landscape with an average seaward gradient of 0.5%. A series of mixed calcareous–siliceous barrier shoreline complexes are preserved across the coastal plain and have formed in response to the high wave energy regime that characterizes this coastline. The barriers comprise eolianite (dune deposits) with interbedded beach and lacustrine facies as well as numerous paleosols (Figure 5). The relict coastal barriers, typically up to 30 m above the general surface of the coastal plain, are between 1 and 2 km in shore normal cross-section, up to 10 km apart, and occur subparallel to the modern coastline. Although composite features, having formed in more than one interglacial highstand, the barriers tend to increase in age landwards.

Preservation of these large-scale coastal landforms is the result of epeirogenic uplift and regional calcrete development. Emergence of the coastal plain has resulted from the combined effects of regional uplift of the Murray Basin in response to plate tectonic interactions between the Indo-Australian and Pacific Plates as part of regional uplift of the southern Australian margin (0.07 m ka^{–1}) and, at a more local scale, crustal doming around the locus of late Quaternary volcanism (0.13 m ka^{–1}; Murray-Wallace *et al.*, 1998; Sandiford, 2003).

The eolianites of the relict coastal barriers have been dated by luminescence and amino acid racemization (whole-rock), and a consistent picture has been derived of barrier formation during interglacial sea-level highstands (Huntley *et al.* 1994; Murray-Wallace *et al.*, 2001). An average rate of uplift of the central portion of the coastal plain based on the altitude of back-barrier lagoon facies, an indicator of former sea level, of 12 successive relict coastal barriers in a transect from Robe to Naracoorte is slow in global terms only, 0.07 mm year^{–1}. Accordingly, intertidal back-barrier lagoon facies of the last interglacial maximum in this region only occur up to 9 m APSL, an order of magnitude lower than for the last interglacial successions on the Huon Peninsula, Papua New Guinea, and imply a eustatic (ice-equivalent) sea level close to present for the last interglacial maximum in this region. The slow rate of tectonic uplift in this region means that mainly evidence for former interglacial highstands is preserved on the coastal plain. The coastal plain succession indicates a general comparability in

the height of successive interglacial highstands. Interglacial sea levels did not deviate by more than 6 m of present sea level for middle and late Pleistocene time, suggesting that the sea returned repeatedly across the continental shelf to a similar regional datum. The data also indicate that significantly higher sea level stands associated with ‘warmer interglacials’ (Burke, 1993) are not expressed in this record. An older barrier succession of presumed early Pleistocene age extends further inland in the Murray Basin, but its age has yet to be reliably determined.

Timing of Quaternary Glacioeustatic Sea-Level Changes

Dating of fossil corals using U-series disequilibrium (U/Th and Pa/Th) represents the foremost method for determining the timing of glacioeustatic sea-level highstands for the latest middle Pleistocene (400–128 ka) and late Pleistocene (128–11.5 ka) records. Radiocarbon dating has been the preeminent method for dating the deglacial sea-level rise following the LGM. Technological developments in the detection of the U-series by thermal ionization mass spectrometry (TIMS) have greatly reduced analytical uncertainties and accordingly refined the resolution with which discrete sea-level highstand events can be dated (Gallup *et al.*, 2002).

The application of laser ablation multicollector inductively coupled plasma mass spectrometry (MC-ICPMS) has significantly enhanced analytical sampling techniques, permitting numerous U-series measurements across individual mollusk and coral specimens (Eggins *et al.*, 2005). This is a significant advance because it permits a more rigorous assessment of the integrity of individual fossils and the degree to which fossils have been contaminated during diagenesis by nonindigenous uranium with the identification of contamination pathways across individual fossils. Collectively, these refinements have led to a clearer definition of the timing of specific sea-level highstands for the last glacial cycle.

Interglacial Sea Levels: Are all Interglacial Highstands of Comparable Magnitude?

One of the interesting and, to some extent, unresolved questions concerning Quaternary glacial cycles is whether sea level during each interglacial highstand attained a similar height. Early studies of former eustatic sea levels in the Mediterranean Basin assumed a progressive lowering of sea level during the Pleistocene, which is now attributed to a tectonic overprint on glacioeustatic sea-level changes.

In the longer geological record, the principal evidence for sea levels during interglacials is inferred from stable isotope records over long time series, particularly for middle and early Pleistocene time. In many respects, stable isotope records from deep-sea and ice cores provide the only means of inferring the magnitude of former high sea-level stands, as the marginal marine stratigraphical record for most of the world’s coastline provides only a fragmentary record of relative sea-level changes for much of early and middle Pleistocene time.

The marine oxygen isotope record shows that in the most general sense, interglacial sea levels were broadly comparable within a band of ±10 m. Stage 11 (423–362 ka) is likely to

Figure 4 Map of the Coorong Coastal Plain in southern South Australia. The coastal plain preserves a record of interglacial highstand barriers (shaded) and back-barrier lagoon deposits. The coastal barrier deposits represented on this map have all formed since the beginning of the middle Pleistocene with the oldest barrier at Naracoorte. The barriers are progressively young toward the modern coastline.

have been the warmest interglacial in the past 500 ka and, as a corollary, characterized by significantly higher sea levels (Burkley, 1993). The suggestion that Stage 11 was characterized by a sea level 20 m APSL (Hearty et al., 1999) remains controversial

because few coastlines have been found to preserve anomalously high coastal facies of this age (Bowen, 2010) and not all oxygen isotope records show evidence for an inferred sea level higher than the last interglacial maximum for Stage 11.

Figure 5 Cross-section of an erosional remnant of the late Pleistocene (marine oxygen isotope substage 5c; ca. 105 ka) coastal barrier, Robe Range at Cape Northumberland, south of Mount Gambier, South Australia. The cliff face is 25 m high. Landward migrating aeolian tabular and trough cross bedding, as well as erosional truncations, are clearly evident. Paleosols and protosols are associated with the principal erosional truncations. Relative sea level was approximately 15 m below present at the time of deposition of the Aeolian dunes. Photograph by Murray-Wallace.

The Last Interglacial Maximum

Arguably one of the most enduring and significant geomorphological expressions of eustatic sea-level changes in the more recent geological record is the last interglacial maximum (OIS substage 5e; ca. 128–116 ka; [Figure 6](#)). For much of the world's coastlines, sediments and landforms of this age occur APSL and in many regions have been used as a regional datum to quantify geodetic changes that have occurred over the past 120 ka ([Bordoni and Valensise, 1998](#); [Murray-Wallace, 2002](#)). In Pacific and Indian oceans, fossil corals remote from plate boundaries consistently indicate former sea levels of between 2 and 9 m APSL ([Hearty et al., 2007](#); [Veeh, 1966](#)), and a more recent review of last interglacial coastal successions and geophysical modeling suggest a 95% probability that global (ice-equivalent) sea level peaked at 6.6 m APSL ([Kopp et al., 2009](#)). A 6-m reference level has been widely cited as a de facto eustatic sea level for the last interglacial maximum, from which corrections have been made for local tectonic deformation. In southern Australia, the most consistent elevation for the last interglacial shoreline is along the Eyre Peninsula (Gawler Craton) coastline where a value of 2 m APSL is recorded along approximately 500 km of coastline ([Murray-Wallace and Belperio, 1991](#)). This area has been geologically stable for the past 1.45 Ga, suggesting that it is particularly suited to quantifying eustatic sea level in the far field of Pleistocene ice sheets. Because the Holocene highstand (7 ka) along this coastline is up to 1 m APSL ([Belperio et al., 2002](#)), the elevation of the last interglacial shoreline is likely to reflect the combined effects of eustatic (ice-equivalent) sea level and hydro-isostasy, and suggests the eustatic sea level for the last interglacial was similar to the Holocene, a finding in accord with geophysical modeling ([Lambeck and Nakada, 1992](#)).

Uranium-series dating has been instrumental in defining the timing and duration of the last interglacial maximum (OIS 5e; [Edwards et al., 1987](#); [Eisenhauer et al., 1996](#); [Muhs 2002](#); [Stirling et al., 1995](#); [Veeh, 1966](#)). Early studies from tectonically

Figure 6 Holocene supratidal flats near the apex of Gulf St Vincent, South Australia that were formerly intertidal flats during the last interglacial maximum, attesting to the general coincidence of sea levels during the Holocene and last interglacial (OIS substage 5e) highstands. Photograph by Murray-Wallace.

uplifted settings such as the Huon Peninsula, Papua New Guinea, where there is a clear physical separation of reef terraces of last interglacial age, revealed evidence for two highstand events. An early phase at 138 ± 5 ka (Reef VIIa) and a late phase at 118 ± 2 ka (Reef VIIb) corresponded with uplift-corrected paleo sea-level culminations of 5 ± 5 m and 6.5 ± 4 m, respectively ([Aharon and Chappell, 1986](#)). High-precision uranium-series dating of corals from Bermuda, the Bahamas, Hawaii, and Australia suggest that sea level during the last interglacial (OIS 5e) was at least as high as present between 128 and 116 ka ([Muhs, 2002](#)).

Other approaches to quantifying the timing and nature of relative sea-level changes during the last interglacial maximum have involved high-resolution sampling of Foraminifera for isotopic analyses from marine cores. Oxygen isotope analyses on the planktonic foraminifer *Globigerinoides ruber* from two cores from the central Red Sea reveal the presence of at least two sea-level oscillations during MIS 5e with the sea-level culminations centered on 123.5 ka and 119.5 ([Rohling et al., 2008](#)). Oxygen isotope measurements on Foraminifera from rapidly deposited marine sediments provide the opportunity to infer glacioeustatic sea-level changes with a greater age resolving power than for coral reefs, given the slow growth response of the latter to rapid relative sea-level changes. The Red Sea record reveals a rate of relative sea-level rise of 1.6 ± 0.8 m per century at the onset of MIS 5e at approximately 123.5 ka when sea-level rose above present levels ([Rohling et al., 2008](#)). The global review of last interglacial coastal successions found that close to the onset of the last interglacial maximum, when sea level was ≤ -10 m, the rate of sea-level rise was at least 5.6 m ka^{-1} ([Kopp et al., 2009](#)). Collectively, these observations are of interest in the context of future projections of global sea-level rise.

Conclusion

The Quaternary has witnessed repeated major changes in eustatic sea level that accompanied the growth and decay of Pleistocene ice sheets and valley glaciers. The principal driving mechanism was insolation changes registered at the surface of the Earth. Globally, the timing and magnitude of these eustatic

changes have tended to conform to a consistent pattern, as indirectly indicated by the marine oxygen isotope record and corroborated by geomorphological and stratigraphical evidence from tectonically uplifted and more stable coastal areas. At a broad scale since at least the start of the middle Pleistocene, glacioeustatic sea-level variations have occurred as part of glacial cycles. These cycles have seen the slow and progressive buildup of continental ice sheets, and concomitant sea-level lowering by as much as 130–120 m over a time span close to 100 ka. High temporal resolution studies of ice cores for the last glacial cycle have indicated short-term (ca. 1460 years) but significant glacioeustatic sea-level changes (9–20 m) associated with major ice breakouts (Heinrich events) in the North Atlantic and illustrate the complexity of eustatic sea-level changes in the recent geological record. Seven glacial cycles have occurred since the start of the middle Pleistocene approximately 780 ka ago. Glacial cycles of the early Pleistocene involved lower amplitude sea-level fluctuations and occurred over shorter periods (41 ka cycles).

This article is a revision of the previous edition article by C.V. Murray-Wallace, volume 4, pp. 3034–3043, © 2007, Elsevier B.V.

Introduction

Eustatic, or ice-equivalent, sea-level change is defined to be the uniform shift in the height of the ocean surface that takes place, in the absence of gravitational and rotational effects, ocean dynamics, and solid Earth deformation, due to the input of meltwater to the ocean (Farrell and Clark, 1976). In reality, noneustatic processes cause sea-level change to be spatially variable, and it is this spatially-variable signal that we sample when we infer past sea levels from field observations.

Eustatic sea-level (ESL) change, the global mean of this spatially varying signal, is an important quantity because it is directly equivalent to the changing mass of the global ice sheets, and it therefore provides an independent method for calibrating the marine oxygen isotope record and the total volume of continental ice at the Last Glacial Maximum (LGM). If we can also identify the source and rate of ice mass change over time, for example using sea-level records, and tie these to past variations in climatic conditions, this will improve our understanding of the response of ice sheets to climate change and provide a baseline for future predictions. Since we do not have complete global records of past sea levels, we use models to understand the processes that cause sea-level change to be spatially variable and interpret the records that have been preserved.

The ocean is not bounded by vertical cliffs, and therefore, changes in ocean mass are accompanied by changes in ocean area. The addition of meltwater increases the surface area of the ocean, while the removal of water, for storage in ice sheets, decreases the surface area of the ocean. This change in ocean area is taken into account in the calculation of ESL by integrating over time:

$$S_{\text{eust}}(t) = -\frac{\rho_{\text{ice}}}{\rho_{\text{water}}} \int_{t_0}^t \frac{\dot{V}_{\text{ice}}(t)}{A_{\text{ocean}}(t)} dt \quad [1]$$

$S_{\text{eust}}(t)$ is the eustatic shift in the height of the ocean surface between time t and some initial time (t_0), ρ_{ice} is the density of ice, and ρ_{water} is the density of ocean water. $\dot{V}_{\text{ice}}(t)$ is the rate of change of grounded ice volume at time t , and $A_{\text{ocean}}(t)$ is the area of the ocean at time t . Equation [1] is a statement of the conservation of mass; it makes the assumption that mass which is lost by the ice sheets is instantaneously gained by the oceans.

Since the end of the LGM at ~20 ka BP, sea-level change has been dominated by the flux of meltwater into the oceans following the deglaciation of the major ice sheets, and it has been postulated that sea-level change in tectonically stable regions far from the major ice sheets (referred to as far-field sites) approximates ESL (Milliman and Emery, 1968). Unfortunately, this is an oversimplification. Sea-level change takes place due to the deformation of either of the two bounding

surfaces: the ocean surface and the ocean floor (Figure 1). Ocean floor deformation is spatially variable and arises, in part, due to changes in ocean and ice loading during a glacial cycle. The temporal average of the ocean surface is a gravitationally equipotential surface, and perturbations to its height are also spatially variable, arising due to the redistribution of solid earth or surface masses, as well as changes in the total mass of ocean water (the eustatic component). Due to the temporally- and spatially-varying interplay between the ocean's bounding surfaces, sea-level change deviates from the eustatic value, even in far-field locations, and the eustatic signal must, therefore, be inferred by comparing observations of sea-level change to model predictions.

The Sea-Level Equation

Glacial isostatic adjustment (GIA) models are used to solve the sea-level equation, which considers sea-level changes due to variations in the mass of water in the ocean (the eustatic component) and sea-level changes due to spatially varying perturbations to the bounding surfaces of the ocean (the isostatic component), in order to predict sea-level change at any point on the Earth's surface:

$$SL(x, t) = S_{\text{eust}}(t) + SL_i(x, t) + SL_o(x, t) + SL_r(x, t) \quad [2]$$

$SL(x, t)$ is the sea level at time t in location x . $S_{\text{eust}}(t)$ is the spatially uniform shift in the height of the ocean surface due to eustatic changes in ocean volume, as defined in eqn [1]. The spatially varying isostatic component of sea-level change consists of perturbations to the ocean floor and ocean surface due to ice loading ($SL_i(x, t)$), ocean loading ($SL_o(x, t)$), and rotational feedback within the Earth system ($SL_r(x, t)$). Due to the viscous memory of the Earth's mantle following loading, these isostatic processes continue to cause sea-level change for thousands of years after the cessation of eustatic changes. A more detailed discussion of the processes that influence sea-level change during a glacial cycle is presented elsewhere in this encyclopedia.

GIA model predictions of sea-level change are dependent upon the ice sheet loading history and the rheology of the Earth. If the predictions do not match the observations, then the ice history and/or earth rheology are altered until a good fit is attained at all sites where sea-level observations are being considered. Once this is achieved, the eustatic signal may be inferred from the ice sheet history.

In Figure 2, we show model predictions of the departure from eustasy at 21 and 6 ka BP, as calculated by Milne and Mitrovica (2008). The predictions are based on the Bassett et al. (2005) deglaciation history and an earth model that is tuned to fit the far-field observations. Red areas in Figure 2(a) and 2(b) indicate regions where relative sea level at 21/6 ka BP

Figure 1 (a) Eustatic sea-level rise due to the influx of meltwater into the ocean. Initial ice and ocean surfaces are shown by solid lines; final ice and ocean surfaces are shown by a dashed line. (b) Isostatic sea-level changes due to (i) ocean surface fall in response to the decrease in the mass of the gravitationally-attracting ice sheet and (ii) ocean floor subsidence due to the increase in ocean loading. Initial surfaces are shown by solid lines; final surfaces shown by dashed lines.

lay above eustatic sea level, and blue areas indicate regions where relative sea level lay below eustatic sea level. The transition from yellow to blue identifies locations where sea level was identical to ESL at 21/6 ka BP. Note that the location of this transition changes between the two times, indicating that there is no location where sea level has tracked eustasy continuously since the LGM (Milne and Mitrovica, 2008). In order to determine ESL changes since the LGM, we seek sea-level records that closely approximate eustasy for each time interval of interest, and interpret each record after accounting for local isostatic effects. The location of such records for the Late Glacial and the Holocene periods are plotted in Figure 2(a) and 2(b), respectively.

A range of sea-level indicators are used when compiling these records. Details of each type are discussed briefly below, but the reader is referred to the relevant Encyclopedia entries for a complete discussion of these data. In all cases, it is important to determine the indicative meaning of any sea-level indicator, that is, the vertical relationship between the altitude of the sea-level indicator and the contemporary tide level (van de Plassche, 1986). A correction may also need to be applied to account for tectonics, subsidence, or compaction. Finally, we account for local isostatic effects before inferring the ESL history. This is carried out by comparing each sea-level record to model predictions, as outlined above.

GIA Modeling

To illustrate this procedure (or at least parts of it), in the following we compare observations of sea-level change to the results from two GIA models. The first, which will be referred to as Bradley et al., combines the results from two recent studies; one which focused on fitting a suite of far-field sea-level data from the LGM to 10 ka BP (Bassett et al., 2005) and another which has been calibrated to Holocene sea-level data from China and the Malay–Thailand Peninsula (Bradley et al., 2008). The Bradley et al. deglacial model is combined with an

Figure 2 Predicted total sea-level change minus the model eustatic component for a time window extending from either 21 cal ka BP (a) or 6 cal ka BP (b) to the present day. The zero line marks where the total sea-level change is equal to the model eustatic value, with red and blue colors indicating sea levels that are, respectively, above and below the eustatic value. Note that the darkest red and blue colors indicate regions where the departure from eustatic sea level is greater than 15 m (a) and 5 m (b). Locations of sites referred to in the text are: Tahiti (Ta), Barbados (Ba), Sunda Shelf (Su), Bonaparte Gulf (Bo), Huon Peninsula (Hu), Jamaica (Ja), Mayotte (My), Malaysia (Ma), East Guangdong (EG), and Cleveland Bay (Cl). Reproduced from Milne GA and Mitrovica JX (2008) Searching for eustasy in deglacial sea-level histories. *Quaternary Science Reviews* 27: 2292–2302, with permission from Elsevier.

earth model whose parameters were chosen to represent average global earth properties; the model has a lithospheric thickness of 96 km and upper and lower mantle viscosities of 0.5×10^{21} and 1×10^{22} Pa s, respectively. These values are typical of those adopted in other GIA studies, and this will be referred to as the optimal earth model for the Bradley et al. GIA model. The second GIA model that we use is ICE-5G (Peltier, 2004). This is combined with a 90 km-thick lithosphere and the 'VM2' viscosity model (Peltier, 2004), which is characterized by a mean upper mantle viscosity of 0.5×10^{21} Pa s and a mean uppermost lower mantle viscosity of 1.6×10^{21} Pa s.

The eustatic component of these two GIA models is plotted in Figure 3. The magnitude and rate of ESL rise predicted by the

Figure 3 Eustatic sea-level changes derived from the Bradley et al. (red) and ICE-5G (black) GIA models.

two models during the last deglaciation is very similar, with total ESL change since the LGM predicted to be in the range 125–130 m, and rates of ESL rise predicted to peak at 20–30 mm year⁻¹ around 14.5 ka BP before dropping below 2.5 mm year⁻¹ from 8 to 7 ka BP onwards. The two GIA models have been tuned, using similar iterative processes, to fit independent datasets of sea-level observations and geodetic data. The differences in the predictions are indicative of the current level of uncertainty in the reconstruction of ESL change since the LGM.

We proceed by discussing, in detail, records of far-field sea-level change for the Late Glacial, Holocene, and late Holocene periods, and compare these to model predictions in order to infer ESL change since the LGM.

Sea-Level Changes During the Late Glacial

The Late Glacial covers the period between the LGM and the final deglaciation of the major continental ice sheets. During the LGM, global grounded ice volume reached its maximum, resulting in a mean lowering of sea level by $\sim 125 \pm 5$ m (Fleming et al., 1998). The LGM is estimated to have persisted from 26 ka BP until 21 ka BP (Clark et al., 2009; Peltier and Fairbanks, 2006; Yokoyama et al., 2000), and can be identified within sea-level records (see Figure 4(a), 4(b), and 4(e)) as a minimum lowstand.

Several outstanding issues remain unresolved with regard to ESL change during the Late Glacial. First, the timing and magnitude of the LGM lowstand can be used to constrain the total volume of ice within the major ice sheets, but not how that volume was distributed (Milne et al., 2002). Secondly, the inferred rise in ESL during the Late Glacial was not uniform, but included several periods of accelerated sea-level rise, commonly referred to as meltwater pulses (mwps). The source of meltwater for the largest of these, mwp-1A, is still the focus of

heated discussion (Gehrels, 2010), while the precise timing, magnitude, and even existence of some of the other mwps is still widely debated (Bard et al., 2010; Gehrels, 2010). In the two GIA models that we use, the Bradley et al. model assumes a dominant mwp-1A contribution from Antarctica, while in the ICE-5G model mwp-1A is primarily sourced from the Northern Hemisphere, with a dominant contribution from the North American ice sheets.

Data from the five far-field sites which have traditionally been used to infer ESL during the Late Glacial are shown in Figures 4(a)–4(e); the locations are shown as black dots on Figure 2(a). Sea-level observations from these sites provide a record of local sea-level change and are not a direct measure of ESL.

Barbados

The Barbados (13.2° N, 59.5° W) sea-level curve (Bard et al., 1990; Fairbanks, 1989; Peltier and Fairbanks, 2006; Figure 4(e)) is the longest and oldest record of sea-level change from the Late Glacial. Observations are derived from fossilized coral samples which have been dated using uranium–thorium (U–Th) and calibrated ¹⁴C to produce a record which extends from 24 to 7 ka BP. The island is located within the Lesser Antilles Island Arc and is undergoing long-term tectonic uplift due to the subduction of the South American plate beneath the Caribbean plate. To account for this, the data have been corrected assuming a steady uplift rate of 0.35 mm year⁻¹ (Peltier and Fairbanks, 2006). The estimated depth range of each coral type is then used to assign an indicative meaning, and hence paleo-sea-level, for each dated observation. This second correction accounts for the large vertical error bars on some of the data.

The extensive Barbados record provides information on the character of the LGM lowstand and post-LGM ESL rise that is not available from other Late Glacial records. The data suggest there was a sustained LGM lowstand, during which ESL remained stationary at an average depth of approximately –120 m (possible range –138 to –115 m) for ~ 5 ka prior to the onset of deglaciation. However, the large vertical errors on the coral samples (*Montastrea annularis*) do not rule out the possibility of an abrupt sea-level rise ~ 22 ka BP (see Peltier and Fairbanks (2006) for further discussion).

Following the LGM lowstand, the data show a continuous rise for 15 ka with sea level reaching 9.5 m below present by 7 ka BP. The rate of sea-level rise over this deglacial period is not steady, with two apparent periods of accelerated, rapid sea-level rise; a 20–24 m jump between 14.2 and 13.8 ka BP and a second, smaller, 15 m rise between 11.5 and 11.1 ka BP. These were the first observations to be defined as mwps (Fairbanks, 1989), respectively mwp-1A and mwp-1B, although it should be noted that they are constrained by gaps in the observational record associated with breaks in the core (Figure 4(e)).

Huon Peninsula

The Huon Peninsula (6° S, 147.5° E) is located in the Western Pacific and experiences the fastest uplift of the five sites selected due to the subduction of the Australian Plate below the Pacific Plate. The sea-level curve (Figure 4(c)) is derived from a

Figure 4 Observed and predicted sea levels at the five Late Glacial far-field sites ((a) to (e)), as shown in [Figure 2\(a\)](#), with [Figure 4](#) (a; inset) displaying data and predictions for the northerly Huon site situated ~ 800 km from the main data set. Black squares and red triangles are sea-level observations, dated using calibrated ^{14}C and U–Th, respectively. Green triangles are recently published, U–Th dated sea-level observations for Tahiti ([Bard et al., 2010](#)). Site-specific sea-level predictions are shown for two published GIA models. Solid black line: ICE-5G with the VM2 earth model ([Peltier, 2004](#)). Solid red line: Bradley et al. ice history with optimal earth model (see main text). The dashed black and red lines represent eustatic sea-level predictions for the ICE-5G and Bradley et al. GIA models, respectively (see [Figure 3](#)).

combination of calibrated ^{14}C ([Chappell and Polach, 1991](#)) and U–Th ([Cutler et al., 2003](#)) dated coral samples. Different tectonic rates have been used to correct the two data sets, $1.76 \text{ mm year}^{-1}$ for the ^{14}C data ([Chappell et al., 1996](#)) and $1.85\text{--}2.8 \text{ mm year}^{-1}$ for the U–Th data ([Cutler et al., 2003](#)). The data infer a steady rise in sea level from -66 m at 13.1 ka BP to -6.5 m at 7.8 ka BP , with no evidence for acceleration during mwp-1B. However, note that there is once again a gap

in the observational record during this period, between 12.1 and 11.2 ka BP .

Tahiti

Tahiti (18°S , 149.5°W) is a ‘hot spot’ volcanic island located within the South Pacific Ocean which undergoes long-term slow subsidence. To account for this, sea-level observations

have been corrected assuming an uplift rate of $-0.1 \text{ mm year}^{-1}$ (Bard et al., 1996) or $-0.25 \text{ mm year}^{-1}$ (Bard et al., 2010). The data are taken from two studies (Bard et al., 1996; Bard et al., 2010) which date a range of coral species from offshore cores using a combination of calibrated ^{14}C and U–Th. The oldest points in the Bard et al. (1996) data set (Figure 4(d)) suggest a rapid 10 m-rise in sea level between 13.8 and 13.4 ka BP, just after the proposed timing of mwp-1A. Although this jump is only constrained using a few data points, preliminary results from a more recent study support these findings (Deschamps et al., 2012). During the proposed time interval of mwp-1B, it is possible to infer a small ($<6 \text{ m}$) jump in the Bard et al. (1996) record; however, as the authors highlighted, when the uncertainty in the depth estimates of the coral samples is taken into consideration, it is equally possible to fit a linear trend to the sea-level rise over this period. Indeed, Bard et al. (2010) present a higher resolution data set and conclude that ‘the Tahiti data define a relatively smooth sea-level rise, with no significant accelerations during the time interval of mwp-1B.’ This highlights the importance of not over-interpreting a sparse data set.

Sunda Shelf

The Sunda Shelf (Hanebuth et al., 2000; Hanebuth et al., 2009) is a geologically stable continental shelf in southeast Asia. The sea-level observations are derived from calibrated ^{14}C -dated organic material (such as mangrove roots, peaty detritus) collected from two offshore drill sites, $\sim 800 \text{ km}$ apart (Hanebuth et al., 2000). The main dataset (shown on the main plot in Figure 4(a)) comes from the southern site (4.75° N , 109.75° E ; Hanebuth et al., 2000; Hanebuth et al., 2009), and a shorter record (shown in the inset on Figure 4(a)) comes from the northern site (9.39° N , 107.99° E ; Hanebuth et al., 2000).

At the southern site, following the LGM lowstand at $\sim 123 \text{ m}$ below present, the rate of sea-level rise is not steady, with two apparent periods of accelerated rise. The first is constrained by the data to be a 10 m jump at 19.6 ka BP. This is of a similar magnitude and timing to the jumps described for the Bonaparte Gulf (see below) and Irish Sea (Clark et al., 2004). However, the global nature of this ‘19 ka event’ is still under debate (Peltier and Fairbanks, 2006). The second jump of $\sim 16 \text{ m}$ between 14.6 and 14.3 ka BP has been associated with mwp-1A, although it is dated to have occurred 500–300 years earlier than the jump in the Barbados record. The shorter sea-level record at the northern site (inset on Figure 4(a)), which covers 13.4 to 10.8 ka BP, shows no evidence for a significant jump or acceleration in the rate of sea-level rise during the mwp-1B event.

Bonaparte Gulf

The Bonaparte Gulf (12° S , 128° E) lies on the broad, tectonically stable continental shelf which surrounds Australia. The sea-level observations (Figure 4(b)) are derived from calibrated ^{14}C dating of organic material (such as marine molluscs) taken from a range of intertidal zones (Yokoyama et al., 2000). Despite the short nature of this sea-level record, it constrains the LGM lowstand between 22 and 19 ka BP to be 122 m below present, and a sharp sea-level rise of $\sim 10 \text{ m}$ is observed at the onset of deglaciation, around 19 ka BP.

Summary

From these five far-field sites, we note several similarities in the pattern of sea-level change during the Late Glacial. First, the magnitude of the LGM lowstand, at $\sim 122 \text{ m}$ below present, is constrained by data at Barbados (Figure 4(e)), Sunda Shelf (Figure 4(a)) and Bonaparte Gulf (Figure 4(b)). At the latter two sites, a rapid (within 1 ka) rise of $\sim 10 \text{ m}$ at 19 ka BP is also observed. Second, there is evidence from Barbados, Tahiti, and the Sunda Shelf to support a brief period of rapid sea-level rise (mwp-1A) during the early deglaciation period, although the precise details are yet to be resolved. Despite evidence for a 15-m sea-level rise between 11.5 and 11.0 ka BP at Barbados (mwp-1B), there is little evidence for an event of this magnitude at other far-field sites. This has led to the suggestion that its magnitude has been overestimated, and that it was not a globally observed event. It has also been postulated that the 8.2 ka BP cooling event was driven by a meltwater pulse, sourced from the drainage of proglacial lakes in North America (Barber et al., 1999). This hypothesis has not yet been confirmed by the sea-level record, and we do not discuss it further here.

Comparisons to Modeling

As mentioned in the Introduction, sea-level observations provide a record of the spatial and temporal pattern of sea-level change at each site and are not a direct indication of ESL. One method to constrain ESL is to compare GIA model predictions of sea-level change with observations of sea-level change at each site. If a good fit is obtained at all sites, then the sea-level equivalent of the ice volume changes that drive the GIA model is taken to be a good approximation of ESL change.

Comparing model predictions of local sea-level change (solid black (ICE-5G) and solid red (Bradley et al.) lines in Figure 4) to the observed data, it is evident that local sea-level change is spatially variable and neither model produces a good fit at all sites. The pre-21 ka BP Barbados data were not available when the GIA models were developed, hence the models are not tuned to fit these data, and predictions are only plotted for 21 ka BP onwards. The magnitude of the local LGM lowstand is captured relatively well at Barbados (Figure 4(e)) and Sunda Shelf (Figure 4(a)) by the Bradley et al. model, but it is over-predicted at Barbados by the ICE-5G model, and both models under-predict the lowstand at Bonaparte Gulf (Figure 4(b)). This misfit could be resolved by adjusting the total ice volume in the input ice model, or, as will be briefly discussed below, by adjusting the choice of earth model. At Huon and Tahiti, the Bradley et al. model provides a closer match to the observed sea level during the Late Glacial than ICE-5G, which under-predicts the observed sea level. However, both models do a good job of predicting the rate of sea-level rise. After $\sim 15 \text{ ka BP}$, the sea-level predictions for Barbados are similar for the two models, and they both fit well, with the predictions bounding the observed data. Prior to 15 ka BP, the Bradley et al. model fits the data better.

The ESL curves derived from the two GIA models are also shown on Figures 4(a)–4(e) and 3 (dashed black and red lines for the ICE-5G and Bradley et al. models, respectively). We reiterate that we do not compare these curves to the sea-level

data, which are representative of local sea level as opposed to ESL, and we refer the reader to [Figure 2](#), where we plot the spatial distribution of the departure from eustasy, to put into context the difference between the local sea level and ESL curves. In particular, note that the observed magnitude of the LGM lowstand or the mwp-1A jump at each site may be higher or lower than the 'eustatic' magnitude. The driving mechanisms behind these differences are discussed in more detail in [Milne and Mitrovica \(2008\)](#).

There are several differences between the ESL histories derived from the two GIA models, including the depth (130 or 125 m) of the minimum ESL at the LGM and the dominant source of meltwater for mwp-1A (either an Antarctic or North American source). The ongoing debate regarding the magnitude (~26 m ESL in both models) and source of mwp-1A has been discussed widely elsewhere ([Gehrels, 2010](#)), and it is now generally believed that the pulse was smaller than initially determined from the Barbados record. The differences between the two ESL histories are primarily due to variations in the volume and timing of melting within the adopted input ice model and to a lesser extent the adopted earth model. At present, there is no optimal global GIA model; the limitations of each must be considered when choosing which to use.

The predictions in [Figure 4](#) have been generated using a single earth model for each GIA model, but, as discussed in greater detail in the Encyclopedia entry on isostasy, sea-level predictions are sensitive to the choice of earth model. To examine this, sea-level predictions at the five far-field sites are generated using the Bradley et al. model ([Figure 5\(a\)–5\(e\)](#)) using four additional earth models. These span a realistic range of upper and lower mantle viscosities, as constrained by previous GIA studies ([Kaufmann and Lambeck, 2002](#); [Mitrovica and Forte, 2004](#)). No single earth model gives the best fit to the data at all sites, and this is to be expected due to the heterogeneous nature of the Earth. The greatest sensitivity is found prior to 15 ka BP, where the local LGM lowstands are predicted to vary over 10–12 m. Some sites are more sensitive to variations in upper mantle viscosity (e.g., Huon and Tahiti) while others are more sensitive to lower mantle viscosity variations (e.g., Sunda Shelf).

Sea-Level Changes During the Holocene

The rate of ESL rise rapidly decreased in the Mid-Holocene following the final deglaciation of the northern hemisphere ice sheets. However, this rate did not immediately reach zero, largely due to the continued input of meltwater from Antarctica throughout the Mid–Late Holocene ([Nakada and Lambeck, 1988](#)), and variations in the volume of the Greenland ice sheet ([Fleming and Lambeck, 2004](#); [Simpson et al., 2009](#); [Tarasov and Peltier, 2002](#)). There exist a large number of observations relating to the local timing of sea-level stabilization or highstand throughout the Indian and Pacific oceans during the Mid-Holocene ([Woodroffe and Horton, 2005](#)), but few continuous records of sea-level change in a single location throughout this period. In [Figure 6](#), we plot data from five sites (shown as black dots in [Figure 2\(b\)](#)) where relatively continuous records

have been obtained, along with predictions of local and ESL change from the two GIA models.

The sea-level indicators used at these sites include shell fragments and beach-rock material from the intertidal zone (China, [Figure 6\(b\)](#)), mangrove and other organic material (Malaysia, [Figure 6\(a\)](#); Australia, [Figure 6\(c\)](#); and Jamaica, [Figure 6\(e\)](#)), fossil microatolls (Australia, [Figure 6\(c\)](#)), fossil oyster beds (Australia, [Figure 6\(c\)](#)), calcareous Foraminifera (Australia, [Figure 6\(c\)](#)), and coral material (Mayotte, [Figure 6\(d\)](#)). ^{14}C dating has been used to establish the age of all the sea-level indicators, with the exception of the coral material, which was dated using U–Th dating. Details of the calibration method used for each dataset can be found in the original data sources, along with details of the indicative meaning of each material and the associated depth errors. We now briefly describe the data and examine how well they are reproduced by the two GIA models.

Malaysia

In [Figure 6\(a\)](#), data from the Straits of Malacca (2.01° N, 102.64° E; [Geyh et al., 1979](#); [Hesp et al., 1998](#)) and Singapore (1.23° N, 103.92° E; [Bird et al., 2007](#)) are combined into one plot because the sites lie within 200 km of each other, and the spatial variation in sea-level predictions across the region is smaller than the errors on the data. No tectonic corrections have been applied to the data as vertical crustal motion in Malaysia is $<0.1 \text{ mm year}^{-1}$ ([Tjia, 1996](#)). A compaction correction is applied to the Singapore data ([Bird et al., 2007](#)), but may be a source of error in the Malacca data set. Both data sets record a sudden decrease in the rate of sea-level rise around 8 ka BP, with the Singapore data recording a hiatus in sea-level rise around 7.7 ka BP ([Bird et al., 2007](#)). The Malacca data then clearly record a ~4 m highstand at ~4.5 ka BP.

East Guangdong, Southeast China

The East Guangdong data (22.64° N, 114.98° E; [Zong, 2004](#)) also record a late Holocene highstand, but it is lower, peaking at ~2 m above present sea level, and occurs later, between ~3.5 and 2.5 ka BP ([Figure 6\(b\)](#)). The rate of early Holocene sea-level rise is much lower at this site than at the Malaysian sites, and the decrease to Mid-Holocene rates is much more gradual. No tectonic corrections have been applied to the data, although the region may be subject to a slight uplift due to the proximity of the plate margin ([Zong, 2004](#)).

Cleveland Bay, Australia

The tectonically stable Australian data ([Figure 6\(c\)](#); 19.89° S, 146.95° E; [Woodroffe, 2009](#)) do not give a clear picture of the rate of sea-level change during the early Holocene due to poor temporal constraints, but they do provide very tight constraints on sea-level changes at this site during the last 5 ka. A highstand of ~2 m is established prior to 6 ka BP, this is maintained beyond 4 ka BP, and then present-day sea level is reached around 2 ka BP.

Figure 5 Comparison of sea-level predictions, for a range of earth models, to sea-level observations at the five Late Glacial far-field sites ((a) to (e)). Symbols for the data are as for [Figure 4](#). All predictions are generated using the Bradley et al. GIA model with a lithospheric thickness of 96 km. The solid red line represents the optimal earth model, as in [Figure 4](#). The dashed lines demonstrate the effect of varying the upper mantle viscosity from 1×10^{20} Pa s (blue) to 1×10^{21} Pa s (green) for a lower mantle viscosity of 1×10^{22} Pa s. The solid lines demonstrate the effect of varying the lower mantle viscosity from 1×10^{21} Pa s (blue) to 5×10^{22} Pa s (green) for an upper mantle viscosity of 5×10^{20} Pa s.

Mayotte

The sea-level data from Mayotte ([Figure 6\(d\)](#); 12.83°S, 45.29°E; [Camoïn et al., 2004](#); [Zinke et al., 2003](#)) are taken from a series of cores in the onshore coral reef and the Mayotte Lagoon. Data from the reef slope were rejected

to ensure that our sea-level curve is reconstructed purely from *in situ* material. We emphasize that a degree of caution should be exercised when using reef material to reconstruct past sea levels since different corals have different indicative meanings, and it is difficult to verify whether coral growth

Figure 6 Observed and predicted sea levels at the five Holocene far-field sites ((a) to (e)), as shown in [Figure 2\(b\)](#). Black squares are sea-level observations as described in the main text. Green squares in [Figure 6\(a\)](#) are the data from [Bird et al. \(2007\)](#), black squares in [Figure 6\(a\)](#) are the data from [Geyh et al. \(1979\)](#) and [Hesp et al. \(1998\)](#). Site-specific and eustatic sea-level predictions are as for [Figure 4](#).

depths remained constant during all rates of sea-level rise. Despite the limited number of data points during the Mid-to-Late Holocene, the data do infer a decrease in the rate of sea-level rise around ~ 8 ka BP, as seen at the other sites, but they do not record a Holocene highstand.

Jamaica

The Jamaican data ([Figure 6\(e\)](#); 18.15° N, 78.11° W; [Digerfeldt and Hendry, 1987](#)) do not extend far enough back in time to quantify the transition from rapid sea-level rise

(prior to 8 ka BP) to slower Mid-Holocene sea-level rates. However, they do provide a very tight constraint on sea-level change from 8 ka BP onwards, and, similar to the Mayotte data, they clearly do not record a Holocene highstand, with sea level remaining close to present from 4 ka BP onwards.

Comparisons to Modeling

The Malaysian data are reproduced very well by the Bradley et al. model, which captures both the slow-down in the rate of sea-level rise and the magnitude and timing of the local highstand. The model does not reproduce the hiatus in sea-level rise around 7.7 ka BP that is hinted at by the high-resolution Singapore data. This inflection may be due to non-GIA vertical land motion, or variations in the melt rate of different ice sheets that are not currently replicated in the GIA model.

The Bradley et al. model also provides a reasonable reconstruction of the East Guangdong data, although the timing of the decrease in the rate of sea-level rise is predicted to take place ~ 1 ka earlier than implied by the data. At both this and the Malaysian sites the ICE-5G model predicts an earlier stabilization of sea-level rates than is observed, indicating that the timing of the cessation of melting in this model requires further tuning, assuming the observations are not biased by non-GIA processes.

It is difficult to determine which GIA model most accurately predicts sea-level change at the Australian site during the final stages of rapid sea-level rise due to the large degree of scatter in the data; however, the magnitude and timing of the local highstand is captured well by both models.

The lack of Holocene highstand at the Mayotte and Jamaican sites is replicated by both models, with the best fit to the Mayotte data provided by ICE-5G model and the best fit to the Jamaican data provided by the Bradley et al. model. Both GIA models predict that Mayotte closely tracks ESL change. Reasons for the variation in Holocene sea-level change at these five sites are discussed further below.

Holocene Sea-Level Highstands

ESL, or global ocean mass, is predicted to have increased monotonically during the Holocene, with rates tending to zero as deglaciation slowed. Observed sea levels at Malaysia, East Guangdong, and Cleveland Bay, Australia, exhibit considerable deviation from this pattern. In these three cases, sea levels rose above present 7–6 ka BP, and peaked 1–5 m above present sea level ~ 5 ka BP, before receding to their current level. This Mid-Holocene highstand is predicted by GIA models (Clark et al., 1978), and is related to the increase in ocean basin capacity during the late Holocene, as we discuss below.

During glaciation, ice loading caused mantle material to be forced laterally out from beneath the major ice sheets, resulting in uplift adjacent to the ice sheets. These ‘peripheral bulges’ are a glacio-isostatic feature, and typically form in oceanic regions. As the ice sheets melted, the bulges began to collapse; a process that continues to the present day due to the viscous properties of the mantle. The subsidence of a peripheral bulge creates additional space within the ocean basins resulting in a global fall in the ocean surface. This process is known as ‘ocean syphoning’ (Mitrovica and Peltier, 1991). Sea-level fall due

to peripheral bulge subsidence is augmented by the hydro-isostatic process of ‘continental levering’ (Walcott, 1972). Shallow continental margins were transgressed toward the end of the Late Glacial, and the associated ocean loading initiated a ‘tilting’ of these margins which results in ocean floor subsidence offshore. Late Holocene ocean-surface lowering due to the influx of water into these subsiding regions is approximately the same magnitude as that due to bulge subsidence (Mitrovica and Milne, 2002). Ocean syphoning has been the dominant contributor to sea-level change at locations far from the former ice sheets since the decline in rate of the eustatic signal. It takes place in the absence of a change in ocean mass; it is not a eustatic change.

A secondary consequence of continental levering is onshore uplift, which enhances the magnitude of a Holocene highstand. The magnitude of this enhancement will vary spatially due to coastal geometry: A site that is situated further inland, for example, at the head of an estuary, will experience greater uplift, and hence will record a higher highstand, than a site at the mouth of the estuary. By modeling the effect of ocean loading along complex coastlines, observations of the differential highstand between two sites enable bounds to be placed upon mantle viscosity (Kendall and Mitrovica, 2007).

The sea-level data from Mayotte and Jamaica do not record a Holocene highstand because the effect of ocean syphoning is balanced by sea-level rise in response to ocean loading and ice loading, respectively. In the first case, the volcanic island of Mayotte is tectonically stable, but its small size means that it moves with the ocean floor, which is currently subsiding due to ocean loading at a predicted rate of $0.13\text{--}0.25\text{ mm year}^{-1}$ (Camoin et al., 2004). The rate of sea-level rise due to subsidence balances the rate of sea-level fall due to ocean syphoning, with the result that this site almost perfectly tracks ESL during the Holocene (see Figures 2 and 6(d)). Jamaica is also subsiding, but due to a different process: It lies on a peripheral bulge which was created as a result of loading by the North American ice sheets. Now the ice has melted, the land is subsiding, and this counteracts the fall in sea level due to ocean syphoning.

Holocene ESL Changes

In general, the data in Figure 6 are fit within error by one of the GIA model predictions (solid lines), and therefore we may place some confidence in the ESL history extracted from the GIA models. Recall that we must rely on model reconstructions to determine past eustatic changes since all sea-level observations are contaminated by local and global (i.e., syphoning) isostatic effects.

Both deglacial models predict continued rapid ESL rise, at rates of $\sim 10\text{ mm year}^{-1}$, from the Late Glacial into the early Holocene. The ICE-5G model then predicts a decrease to $\sim 1.5\text{ mm year}^{-1}$ between 8 and 7 ka BP, while the Bradley et al. model adopts a gradual decrease 7–5 ka BP, concurrent with the final deglaciation of the Laurentide ice sheet. Between 7 and 4 ka BP, the ICE-5G model predicts $\sim 3.5\text{ m}$ ESL change due to ongoing melting of the Antarctic ice sheet, whereas the Bradley et al. model predicts a contribution of $\sim 5.5\text{ m}$ ESL from Antarctica since 7 ka BP. In the latter model, ice mass loss continues through to 2 ka BP, after which the eustatic

Figure 7 Comparison of sea-level predictions, for a range of earth models, to sea-level observations at the five Holocene far-field sites ((a) to (e)). Symbols for the data are as for [Figure 6](#), model predictions are as for [Figure 5](#).

contribution to sea-level change drops to zero. The Bradley et al. model is similar to [Lambeck's \(2002\)](#) eustatic reconstruction between 7 and 5 ka BP, and all three models are similar from 4 ka BP onwards. In the late Holocene, the ICE-5G model differs slightly from the other models in that it assumes that the mass of the Greenland ice sheet dropped below its present value by ~ 0.1 m ESL around 1 ka BP, before readvancing to its present extent at the beginning of the twentieth century.

Such high-resolution details of the recent ESL history must be resolved using near-field sea-level and ice-sheet data, as the majority of far-field data lack the required precision.

As in the case of the Late Glacial predictions (see [Figure 5](#)), the Holocene sea-level predictions are dependent upon the assumed earth structure as well as the deglaciation history ([Figure 7](#)). This factor is of lesser importance in the Holocene due to the smaller amplitude of mass redistribution over the

surface of the Earth during this period. However, the predictions still exhibit a significant degree of sensitivity in regions which experience the most deformation (e.g., Jamaica), and, as mentioned previously, highstand magnitudes are sensitive to mantle viscosity (e.g., East Guangdong, Malaysia).

Sea-Level Changes During the Late Holocene

For the last ~ 100 years, direct measurements of sea-level change have been recorded by tide gauges, supplemented in the last 15 years by satellite altimetry data, yielding a present-day eustatic rate of $\sim 2 \text{ mm year}^{-1}$ (Cazenave et al., 2009). An active area of sea-level research lies in trying to bridge the gap between the instrumental record and the paleo-record in order to place current rates of ESL rise into a longer-term context. This requires sea-level indicators that (i) cover the last few millennia, (ii) can accurately resolve decimeter-scale changes on 100-year time scales, and (iii) have a chronology that extends into the early twentieth century. Three key data sets have currently been utilized: microatolls, salt marshes, and archaeological sites (see the relevant Encyclopedia entries).

Microatolls are highly sensitive to small sea-level changes at low latitudes, and have been used to reconstruct late Holocene sea-level change in the Southern Cook Islands (Goodwin and Harvey, 2008). At this southern Pacific location, ocean syphoning caused sea-level to fall at $0.4\text{--}0.8 \text{ mm year}^{-1}$ throughout the majority of the last millennium until modern sea-level rise reversed this trend.

Salt marshes provide an excellent record of millennial-scale sea-level change (Long et al., 2010), but they are mostly found outside the tropics, where ESL changes are likely to be overprinted by isostatic effects. However, Gehrels et al. (2006) have successfully used salt marsh records to reconstruct slow rates of ESL fall during the last millennium and demonstrate that contemporary rates of ESL rise are $1\text{--}2 \text{ mm year}^{-1}$ greater than late Holocene rates.

Archaeological data also indicate slow rates ($<0.2 \text{ mm year}^{-1}$) of ESL fall during the last millennium, and can be used to place bounds on the timing of the onset of modern sea-level rise (Lambeck et al., 2004).

However, a degree of caution must be applied to the interpretation of high-resolution observations of sea-level change during the last few hundred years. Aside from GIA, spatially-variable sea-level change takes place due to variations in the temperature and salinity profile of the oceans and perturbations to atmospheric and oceanic circulation patterns, on multiannual to multidecadal time scales. The magnitude of sea-level change induced by these processes can be several times current eustatic rates, as demonstrated by the present-day range of sea surface displacement rates recorded by satellite altimetry (Figure 8). Several decades of observations are therefore required to isolate the GIA signal from the 'dynamic' signal (Kopp et al., 2010). Since low rates of eustatic change have persisted for the majority of the last 2–3 ka, care must also be taken to verify that observations from this period can be attributed to GIA, and not other causes of local sea-level change.

Summary

ESL change is the change in the height of the ocean surface, in the absence of gravitational and rotational effects and solid earth deformation, due to an influx of ocean mass in the form of meltwater. In reality, sea-level change varies continuously in space and time due to the aforementioned gravitational and rotational effects and solid earth deformation, and consequently there is nowhere where the eustatic change can be directly measured. ESL change must be inferred, using GIA models to interpret records of sea-level change. We present a comparison of ten far-field sea-level records with predictions derived from two GIA models. While these records closely approximate ESL changes, they contain additional isostatic and tectonic components, and must be interpreted with this in mind. The close fit between observations and predictions verifies the accuracy of the GIA models, with any misfit

Figure 8 The regional change in sea level based on the 17-year trend from 1993 to 2009 calculated using radar altimeter data from several satellites. Reproduced from Figure 1 of Willis et al. (2010) Global sea level rise: Recent progress and challenges for the decade to come. *Oceanography* 23(4): 26–35, with permission.

attributed to incorrect assumptions of ice history or earth rheology, or the influence of non-GIA processes. The eustatic history inferred from the GIA models (**Figure 3**) is characterized by a lowstand between ~26 and ~21.5 ka BP, followed by rapid ESL rise until ~7 ka BP, with rates peaking at 20–30 mm year⁻¹ around 14.5 ka BP, then a much slower rate of increase (<2.5 mm year⁻¹) which tends to zero by 3–2 ka BP. During each period, rates varied due to dynamic ice sheet processes.

Isostasy: Glaciation-Induced Sea-Level Change

G Milne, University of Ottawa, Ottawa, ON, Canada

Introduction

Relative sea level (RSL) is defined as the height of the ocean surface relative to the solid Earth (or ocean floor) and can be defined at any location within the oceans. Changes in RSL are driven, therefore, by processes that produce a height shift in either of these two bounding surfaces. At any given location, RSL changes over a wide range of time scales with characteristic periods ranging from less than a second to millions of years. This broad spectrum of time variation reflects the variety of processes that drive RSL changes, such as atmospheric circulation, ocean circulation, lunar tides, deformation of the solid Earth associated with internal buoyancy forces (mantle convection), and changes in the distribution of mass at the Earth's surface (e.g., growth and melting of ice sheets, erosion and deposition of rocks).

During the Quaternary, the dominant component of the RSL change observed using proxy records was driven by the accumulation and ablation of major ice sheets. There are a number of physical mechanisms associated with this glaciation-induced sea-level change and these are described in the following section. Models that incorporate these mechanisms can be employed to predict RSL changes which can, in turn, be compared to the observations. It is through this modeling procedure that researchers have been able to better understand the physical processes involved in driving the sea-level changes as well as place constraints on key model parameters. The most common applications of this type will be presented in the section titled 'Applications of Isostatic Sea-Level Models.'

Physical Principles of Glaciation-Induced Sea-Level Change

Vertical Deflection of the Solid Earth Surface

The late Quaternary ice sheets reached thicknesses of several kilometers in places. During a typical glacial cycle, the net flux of mass from the oceans to the ice sheets and back again is on the order of 100 m of eustatic sea-level change. Note that this quantity is also referred to as 'ice-volume equivalent sea-level change' (Lambeck and Chappell, 2001). This redistribution of surface water mass is large enough to cause a significant isostatic deformation of the solid Earth. This deformation is one of the key processes that contributes to glaciation-induced sea-level change (e.g., O'Connell, 1971; Chappell, 1974; Peltier and Andrews, 1976; Clark et al., 1978).

Figure 1 shows a model prediction of vertical solid Earth deformation at present associated with the most recent deglaciation (ca. 20–7 cal ka BP). The signal is dominated by crustal uplift in regions where large ice sheets once existed (e.g., North America, Eurasia) or where the extent and thickness of ice was larger than at present (e.g., Antarctica). Even though ice had

disappeared in North America and Eurasia during the early to mid-Holocene, there remains a significant uplift in these regions due to the relatively high viscosity of mantle material, which limits the rate at which the solid Earth can attain isostatic equilibrium following the removal of ice. Note that there are extensive regions of subsidence peripheral to areas of uplift. This deformation is linked to uplift of the solid Earth in regions peripheral to the growing ice sheets; during deglaciation, this process is reversed and these so-called 'peripheral bulges' subside.

The solid Earth deformation associated with changes in ice mass distribution, known as 'glacioisostasy,' is a dominant contributor to RSL in regions near major ice centers (so-called 'near-field' regions). A significant amount of deformation is also caused by the changes in sea level associated with the changes in ice distribution. The solid Earth deformation associated with this ocean loading, known as 'hydroisostasy,' is most apparent in regions far removed from the major ice centers (so-called 'far-field' regions), where the glacioisostatic signal is considerably reduced. For example, the small uplift around the periphery of Australia and Africa in Figure 1 is associated with the positive ocean load applied around these continents during deglaciation. This uplift has been termed 'continental levering' (e.g., Clark et al., 1978).

The surface mass redistribution and subsequent solid Earth deformation associated with Earth glaciation perturbs the Earth's inertia tensor and therefore affects a change in Earth rotation: commonly described as a change in the spin rate (change in length of day) and a change in the orientation of the spin axis relative to the solid Earth (True Polar Wander; e.g., Sabadini et al., 1982; Mitrovica et al., 2005). The latter of these produces a significant global-scale deformation of the Earth due to the corresponding shift in the rotational potential. The dominant geometry of this deformation is shown in Figure 2. This rotation-induced pattern of deformation is relatively small (approximately 1–2 orders of magnitude less than the glacioisostatic signal), and so is difficult to see in Figure 1. The signal is most evident as a subtle and broad uplift near South America and north-west Asia, and as broad regions of subsidence centered on North America and Australia (the North American component of the signal is masked by the much larger glacioisostatic deformation).

Vertical Deflection of the Ocean Surface

As discussed earlier, the vertical position of the ocean surface is perturbed due to a variety of processes (winds, ocean circulation, tides, etc.). Over time scales of 100s to 1000s of years, the mean height of the ocean surface approximates the geodetic surface known as the geoid, which is an equipotential of the Earth's gravitational field. Therefore, for the purposes of modeling secular sea-level changes associated with Earth glaciation,

Figure 1 Predicted present-day vertical motion of the solid Earth based on a model of glacial isostatic adjustment. The ice component of the model is adapted from the ICE-5G deglaciation history (Peltier, 2004).

Figure 2 Schematic diagram illustrating the geometry of the vertical solid Earth deformation driven by a clockwise wander of the rotation pole between the times t and t^+ . Shaded areas indicate uplift and nonshaded areas indicate subsidence (due to the associated perturbations in the rotational potential). Reproduced from Mound JE and Mitrovica JX (1998) True polar wander as a mechanism for second-order sea-level variations. *Science* 279: 534–537, with permission.

vertical deflections of the ocean surface are determined by considering changes in the Earth's gravity field (or geopotential).

Any redistribution of mass on or within the Earth will affect the geopotential and therefore perturb the ocean surface. The height shift of the ocean surface caused directly by the flux of mass on the Earth's surface between ice sheets and oceans during glaciations and the changing rotational potential is known as the 'direct effect' (e.g., Clark et al., 1978). The direct influence of the rotational potential on the mean sea surface

exhibits the same geometry as the perturbation to the solid Earth surface (Figure 2). The direct effect associated with an ablating ice sheet is illustrated schematically in Figure 3. Between the two time steps, t_0 and t_1 , the ice sheet loses mass and therefore the gravitational pull of the ice on the ocean water relaxes, causing a lowering of the ocean surface proximal to the ice and a height increase of the ocean surface in the far field. Note that the redistribution of ocean water has a similar effect – for example, regions characterized by a sea-level rise will experience a greater rise due to the increased gravitational pull of a deeper water column.

The perturbation to the geopotential due to the deformation of the solid Earth by the surface ice-ocean loading and changing rotational potential is termed the 'indirect effect' since it is a consequence of the solid Earth response to these changes. The spatial pattern of the present-day sea-surface height change as a consequence of the indirect effect will resemble that shown in Figure 1 (albeit a smoother version of this pattern). For example, the mass influx of solid Earth material to uplifting regions causes an increase in the local geopotential and therefore produces a steady rise in the mean ocean surface. Note, however, that the rates of sea-surface height changes driven by Earth deformation will be approximately an order of magnitude less than those for vertical land motion in Figure 1.

Mass Conservation

An important criterion that must be satisfied when calculating sea-level change associated with the growth and ablation of ice sheets is that the mass lost (gained) by the ice sheets is gained

Figure 3 Schematic diagram illustrating the influence of an ablating ice sheet on the vertical displacement of the solid surface and the time-averaged ocean surface (or geoid). A short time interval is assumed (~ 100 years) so that the Earth deformation is largely elastic and of relatively small amplitude. As a result, the spatial variation in ocean surface height change is dominated by the gravity perturbation due to surface mass exchange between the ice sheet and the ocean (i.e., the direct effect). The dotted lines in (b) denote the position of these two surfaces in (a). The difference between the solid and dotted lines in frame (b) illustrates the uplift of the solid Earth immediately under the ablating ice mass and the subsidence of the solid Earth peripheral to the ice mass; it also shows the height shift of the ocean surface. Note that the latter is characterized by a fall near the ice mass and a rise at a greater distance from the ice mass. Reproduced from Tamisiea ME, Mitrovica JX, Davis JL, and Milne GA (2003) Long wavelength sea level and solid surface perturbation driven by polar ice mass variations: Fingerprinting Greenland and Antarctic ice sheet flux. *Space Science Reviews* 108: 81–93, with permission.

(lost) by the oceans to ensure that the total amount of water within the system is conserved. This criteria is satisfied by

$$\iint_{\text{ocean}} S(\theta, \varphi, t) dA = V_{\text{OW}}(t) = -\frac{\rho_i}{\rho_w} V_I(t) \quad [1]$$

in which $S(\theta, \varphi, t)$ is the change in sea level since a reference time (e.g., the onset of ice growth); $V_{\text{OW}}(t)$ and $V_I(t)$ are, respectively, the changes in the volume of ocean water and grounded ice since the reference time; and ρ_i and ρ_w are the densities of ice and water, respectively. Note that the influence of changes in temperature is not considered in eqn [1].

To satisfy eqn [1], the mean ocean surface cannot remain on the same equipotential of the Earth's gravity field. To simulate this in the model, a globally uniform shift in the height of the ocean surface is applied (e.g., Farrell and Clark, 1976; Mitrovica and Peltier, 1991). The amplitude of this shift is governed by two processes: the change in ocean water volume associated with ice sheet growth/melting (known as 'eustatic sea level') and the volumetric change in the height shift between the ocean surface and the ocean floor due to the processes described in the previous two subsections. In the former case, for example, the increase in ocean water volume during deglaciation will cause the ocean surface to rise, on average, and therefore lie on an equipotential further displaced from the Earth's center. The second of these two processes leads to the mechanism known as 'ocean syphoning' (Mitrovica and Peltier, 1991; Mitrovica and Milne, 2002).

Ocean syphoning is driven by two aspects of glaciation-induced sea-level change – these are illustrated in Figure 4. Figure 4(a) shows the contribution to syphoning associated with peripheral bulge subsidence. A dominant proportion of

Figure 4 Schematic diagram illustrating the syphoning mechanism. (a) Shows the lowering of the ocean surface caused by the syphoning of ocean water into subsiding peripheral bulge regions adjacent to major glaciation centers during and subsequent to periods of deglaciation. (b) Illustrates the similar effect caused by subsidence around all continental margins due to hydroisostasy during and following periods of deglaciation. Reproduced from Mitrovica JX and Milne GA (2002) On the origin of late Holocene highstands within equatorial ocean basins. *Quaternary Science Reviews* 21: 2179–2190, with permission.

peripheral bulges are located in oceanic regions and so the subsidence of these regions during deglaciation contributes to a significant, spatially uniform fall in sea level. [Figure 4\(b\)](#) illustrates the contribution of continental levering to the syphoning process during deglaciation (again, giving a sea-level fall). In total, the magnitude of the global mean sea-level fall due to syphoning during deglaciation is a few 10s of meters from the Last Glacial Maximum (LGM) to present and is about 0.3 mm year^{-1} at present (the magnitude of the signal depends on the rate of solid earth motion which is governed by the Earth's internal viscosity structure).

Sea-Level Equation

All of the previously described processes can be represented in a single equation that can be solved to predict sea-level change over the world's oceans due to Earth glaciation. [Farrell and Clark \(1976\)](#) were the first to present and solve a version of the sea-level equation. Since their seminal work, a number of extensions have been made to the theory built into the equation as well as the methods applied to solve it. Solving the sea-level equation is nontrivial since the quantity being solved for is a component of the surface load that influences sea level. Most of the methods used involve an iterative procedure and the most popular of these is the so-called 'pseudospectral technique,' which was first applied to the sea-level problem by [Mitrovica and Peltier \(1991\)](#).

The primary theoretical extensions to the original theory of [Farrell and Clark \(1976\)](#) include the incorporation of shoreline migration, the influence of changes in Earth rotation, and a more accurate treatment of sea-level change in regions with ablating marine-based ice (see [Milne, 2002](#) for a review). The most recent form of the sea-level equation that incorporates all of these recent improvements in an accurate, generalized theory was published by [Mitrovica and Milne \(2003\)](#) and can be solved efficiently by an algorithm that is based on the pseudo-spectral method ([Kendall et al., 2005](#)).

Applications of Isostatic Sea-Level Models

Introduction

The previous section describes the processes that govern sea-level change due to mass changes in land ice. These processes are embedded in the sea-level equation, which is solved within the framework of a model of glacial isostatic adjustment (GIA). In essence, a GIA model is defined by two elements: a model of the Earth forcing and a model of solid Earth structure and rheology ([Figure 5](#)). The Earth forcing is specified by defining the surface load (ice-ocean mass redistribution) and the time-varying rotational potential. The ice component of the load

Figure 5 Schematic diagram illustrating the main components comprising a model of glacial isostatic adjustment.

model is commonly developed using constraints from a variety of disciplines, including glacial geology, glaciology, and GIA (see the section 'Inferring Late Quaternary Ice Histories'). The ocean load model is calculated by solving the sea-level equation for a specified ice model and Earth model. In most previous studies, the adopted Earth model has a spherical geometry and internal structure that varies with depth only.

The primary aim of this section is to describe how the Earth and ice components of a GIA model are constructed and then tested by comparing model predictions to sea-level observations, and some of the issues involved in doing this accurately.

Inferring Earth Viscosity Structure

The isostatic response of the solid Earth, for a given load history, is governed by its internal density and rheological structure. To a first approximation, this structure is spherically symmetric (i.e., is depth-dependent only) and so the majority of Earth models previously employed for this purpose have not incorporated lateral variations in these properties. The rheological model applied is most commonly that of a Maxwell viscoelastic material – which simulates both an elastic and (linear) viscous component of the deformation. It is important to include an elastic component given that land ice extent can change significantly within a relatively short time (order 10–100 years).

The elastic and density structure of Earth models applied to problems of glaciation-induced sea-level change is taken from seismic constraints, whereas the viscosity structure is one of the parameter sets that can be inferred when modeling GIA data sets such as RSL change. The viscosity structure of the deep Earth is a primary control on a number of geodynamic processes, including mantle convection, and there are a limited number of methods that can be applied to infer this structure (e.g., [Ranalli, 1995](#)). This application of the model is therefore one of the more important elements in sea-level modeling studies (e.g., [Cathles, 1975](#); [Peltier, 1998](#); [Lambeck and Johnston, 1999](#)).

The viscosity structure in spherically symmetric Earth models is parameterized into a small number of layers. The most common parameterization comprises three layers. The lithosphere, the upper layer, is given a very large viscosity (10^{30} – $10^{50} \text{ Pa s}^{-1}$), so that it behaves as an elastic layer on late Quaternary time-scales – the thickness of this layer is the variable parameter. The second layer extends from the base of the model lithosphere to the 670-km deep seismic velocity discontinuity and the third layer extends from this depth to the core–mantle boundary. These two layers represent the model upper and lower mantle, respectively, and are each assigned a single viscosity value that is a free parameter in the modeling. Note that a number of studies have considered other depth parameterizations (e.g., [Lambeck et al., 1996](#)), and inverse modeling studies commonly parameterize viscosity into a much larger number of layers beneath the lithosphere (e.g., [Forte and Mitrovica, 1996](#); [Peltier, 1998](#)).

As indicated in [Figure 1](#), the largest magnitude of solid Earth deformation is found in areas that have experienced the largest changes in ice extent (e.g., North America, Fennoscandia). For this reason, sea-level observations from regions such as these have been most commonly adopted to infer viscosity

structure. One primary limitation of modeling near-field data is that the model predictions are sensitive to both viscosity structure and the ice history. The accuracy of the viscosity inference will depend on the accuracy of the ice model (see the section 'Inferring late Quaternary ice histories'). This ambiguity can be addressed to some extent by simultaneously modeling for both the ice history and the viscosity structure and performing sensitivity studies to determine the degree of parameter trade-off between these two components of the model (e.g., [Lambeck et al., 1998](#)).

An alternative approach to addressing this issue of non-uniqueness involves identifying a parameterization or subset of the data that is relatively insensitive to one of either the viscosity model or ice model. Two parameterizations of near-field sea-level data that have been shown to reduce the sensitivity of the predictions to the ice history are the 'decay-time' parameterization ([Mitrovia and Peltier, 1993](#)) and the 'relaxation spectrum' derived from mapping out the elevation of ancient shorelines in Fennoscandia ([McConnell, 1968](#)).

A third approach to reduce the sensitivity of the data to uncertainty in the ice component of the model involves the application of far-field sea-level data. By definition, these observations are obtained in areas distant from the major glaciation centers and so the glacioisostatic signal will be relatively small. However, the observations are sensitive to the ice loading, largely through eustatic sea level as well as gravitational and rotational changes. These components of the total sea-level signal have very long wavelengths and so by differencing sea-level observations corresponding to the same time from localities within the same region largely removes the eustatic and glacioisostatic signals. The residual signal is dominated by hydroisostasy. This parameterization of far-field data was pioneered by [Nakada and Lambeck \(1989\)](#) who modeled differential Holocene highstand observations from the Australian region to obtain a robust inference of Earth viscosity structure.

Most inferences of Earth viscosity structure have been based on forward modeling analyses. However, the information obtained from the application of inverse methods has played an important role in partly reconciling the differences in inferences made by various groups ([Mitrovia, 1996](#)). Specifically, the explicit consideration of depth-resolving power in inverse analyses has clearly identified how well a particular set of sea-level data can constrain the depth variation of viscosity. Analyses of this type have shown that the depth-resolving power of a given sea-level data set depends on the spatial extent of the local ice sheet and the viscosity structure within the mantle. The relatively small number of inverse modeling studies performed to date have shown that sublithosphere viscosity structure can be uniquely resolved in only two to three layers for any specific regional data set, with a maximum depth constraint extending to ~ 1800 km for data associated with the deglaciation of the North American ice sheets (e.g., [Mitrovia, 1996](#)).

The limited resolving power of sea-level data has been addressed by inverting these data jointly with other GIA data sets (e.g., [Kaufmann and Lambeck, 2002](#)) and data related to convective flow within the mantle (such as the global free air gravity anomaly, and motion of the tectonic plates) (e.g., [Forte and Mitrovia, 1996](#); [Mitrovia and Forte, 2004](#)). With regard

to the viscosity constraint provided by RSL observations, an optimal resolving power would be obtained by jointly modeling data from regions once covered by ice sheets with a different geographic extent (e.g., the British Isles, Eurasia, and North America).

The real Earth is known to exhibit significant departures from spherical symmetry. With dramatic improvements in computational power, a growing number of groups have begun to model sea-level changes using global three dimensional (3D) Earth models (e.g., [Paulson et al., 2005](#); [Wu et al., 2005](#); [Wang et al., 2008](#)). A primary aim of these studies has been to determine the significance of the 3D structure in predicting sea-level changes in order to assess the extent to which inferences of viscosity and ice histories (see next subsection) based on 1D Earth models might have been biased.

A second important initiative with respect to modeling the isostatic component of the Earth response has been the consideration of rheologies that incorporate transient creep (e.g., [Peltier et al., 1981](#)) or nonlinear viscous flow (e.g., [Wu, 1999](#); [Wu and Wang, 2008](#)). A large number of studies on the deformation of rocks and minerals at high pressures and temperatures in the laboratory have shown that, under a wide range of conditions, mantle rocks will deform in a nonlinear, power law fashion (e.g., [Drury and Fitzgerald, 1998](#)). It is expected that linear and nonlinear viscous flow will dominate in different parts of the sublithospheric mantle. A small number of studies have considered models that include both linear and nonlinear flow (e.g., [van der Wal et al., 2010](#)).

The consideration of lateral variations in Earth model structure and more sophisticated (non-Maxwell) rheologies increases the level of complexity within GIA sea-level models and therefore the degree of nonuniqueness in obtaining model solutions. It remains to be seen just how large an impact these developments will have in this regard.

Inferring Late Quaternary Ice Histories

A second important application of sea-level modeling is the inference of more accurate ice sheet reconstructions – particularly for the period following the LGM during which there is a relative abundance of high-quality RSL data. Constraining the evolution of the Earth's ice sheets during the late Quaternary is addressed within three research disciplines: GIA, Glaciology, and Glacial Geology.

The strong impact of ice sheets on other components of the climate system has become evident through the application of general circulation models of climate change, in which reconstructions of ice sheet evolution are commonly input as a boundary condition. A continued effort to employ RSL observations to better constrain such reconstructions is clearly important to complement information derived from glaciological observations and modeling as well as field-based geological and geophysical studies.

As discussed in the previous subsection, near-field sea-level data can be employed to develop regional and global reconstructions of ice sheets (e.g., [Tushingham and Peltier, 1991](#); [Lambeck, 1993](#); [Lambeck et al., 1998](#)). In the majority of previous studies, little to no glaciological constraints (relating to the physics of ice flow and surface topography) were employed in arriving at the final reconstructions. Some more

recent studies have addressed this issue by using numerical models of ice sheet flow forced by climate (e.g., [Tarasov and Peltier, 2002](#); [Simpson et al., 2009](#)). While the application of these models introduces a larger number of variables to the problem, the resulting reconstructions are more realistic and can be used to infer additional information regarding the mechanisms that governed the evolution of the ice sheet(s).

The veracity of past ice sheet reconstructions depends largely on the quality of the data employed in their construction (sea level and other), the accuracy of the models applied (GIA/glaciological), and the significance of any trade-offs between earth and ice model parameters. As discussed in the previous subsection, an efficient way in which to reduce the ambiguity due to parameter trade-off is to identify parameterizations or subsets of the data that are relatively insensitive to either the Earth or ice component of the model. For example, employing a viscosity model that is based on the decay-time parameterization (which is relatively insensitive to the ice loading model; see previous subsection) to derive an ice sheet reconstruction would be an efficient way to minimize the non-uniqueness problem inherent within near-field sea-level data.

On account of their distance from the major glaciation centers, far-field RSL data exhibit a primary sensitivity to mass flux between the ice sheets and oceans. For this reason, when the data are corrected for the processes that cause the total signal to deviate from the eustatic component signal (due to glacio- and hydroisostasy, syphoning, etc.; see previous section 'Physical Principles of Glaciation-Induced Sea-Level Change'), they provide a useful measure of the total volume of grounded ice on the Earth's surface in the past compared to the present, which can be compared to, or used to calibrate, ice volume estimates based on oxygen isotope records.

Estimates of grounded ice volume at the LGM have converged within the past few years and generally lie within the range 120–135 m of eustatic sea-level change (e.g., [Lambeck et al., 2002](#); [Milne et al., 2002](#); [Peltier, 2004](#)). These estimates serve as an important constraint which global LGM ice sheet reconstructions must adhere to. Note that the most recent estimates of LGM ice volume support the CLIMAP 'minimum model' with 127 m of eustatic sea-level lowering compared to the 'maximum model' with 163 m ([CLIMAP, 1981](#)).

The modeling of post-LGM far-field RSL data has greatly enhanced our understanding of the rate and sources of glacial melting from the LGM to the present. Far-field observations have been interpreted to support the existence of a series of very rapid and short-lived melting events during the most recent deglaciation. For example, from the LGM to the Late Glacial, three such events have been proposed:

- ~19 cal ka BP (10–15 m; [Yokoyama et al., 2000](#));
- ~14 cal ka BP (20–30 m; [Fairbanks, 1989](#); [Bard et al., 1990](#)); and
- ~11.5 cal ka BP (10–15 m; [Fairbanks, 1989](#); [Bard et al., 1990](#)).

For a more detailed discussion of data relating to these proposed rapid events, see elsewhere in the encyclopedia. Determining how these so-called 'meltwater pulses' relate to other large and rapid climate events during this period is central to our understanding of deglacial- and millennial-scale climate change. A necessary first step toward this aim involves

determining which ice reservoirs were the primary contributors to these events. Isostatic sea-level models have provided useful information in this regard.

In far-field locations, the direct gravitational effect of ice sheet ablation (see [Figure 4](#) and related discussion) is the mechanism that dominates the spatial variation in the predicted far-field sea-level signal during rapid melt events. The contribution from solid Earth isostatic deformation is relatively minor and so, given an appropriate spatial distribution of data that capture a specific meltwater pulse, it is possible to obtain relatively robust constraints on the global-scale melt source geometry for that event. The first studies of this kind have shown, for example, that the existing far-field data favor a dominant Antarctic rather than North American source for the ~14 cal ka BP event ([Clark et al., 2002](#); [Bassett et al., 2005](#)). This melt source model can be tested further and spatially refined by modeling near-field sea-level data from near-field regions.

A number of far-field RSL observations display a high stand during the mid-Holocene. Sea-level modeling has shown that this high stand results from a dramatic decrease in the rate of glacial melting around this time, which leads to the subsequent sea-level fall through the operation of ongoing isostatic effects, primarily syphoning and hydroisostasy ([Clark et al., 1978](#); [Mitrovica and Peltier, 1991](#)). The shape (e.g., smooth or sharp), timing, and magnitude of these high stands is controlled by both the isostatic response of the solid Earth and the rate and magnitude of glacial melting. The isostatic component can be effectively isolated and therefore modeled by considering spatial differences in the observed sea-level high stands ([Nakada and Lambeck, 1989](#); see previous subsection). The solid Earth component can then be predicted and removed from the observations, leaving a residual RSL signal for the period during and following the high stand that provides a direct measure of when and how abruptly the most recent deglaciation ended and the history of global-scale melting after this time (e.g., [Fleming et al., 1998](#); [Peltier, 2002](#)). The latter serves as an important reference value with which to compare estimates of global mean sea-level rise during the twentieth century (e.g., [Lambeck, 2002](#)).

Conclusion

Changes in RSL during the Quaternary are dominated by large-scale glaciation. A number of physical mechanisms contribute to glaciation-induced sea-level changes through their influence on the relative vertical height between the ocean floor and the ocean surface. These physical mechanisms provide the theoretical basis of the so-called sea-level equation, which can be solved to generate predictions of glaciation-induced sea-level changes for a prescribed Earth and ice model. These predictions can be compared to observations to test the accuracy of the model and to infer model parameters. With respect to the Earth model, the majority of such studies have focused on inferring the viscosity structure within the mantle. This structure is a primary control on a variety of geodynamic processes that involve the solid-state creep of mantle material. With respect to the ice model, the majority of such studies have focused on inferring the

space–time history of regional-scale ice extent using near-field sea-level data, as well as the time variation in global (grounded) ice volume, during and following the LGM. This information has played a key role in advancing our understanding of Ice Age climate change.

Use of Cave Data in Sea-Level Reconstructions

A Dutton, University of Florida, Gainesville, FL, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

The use of radiometrically dated cave deposits offers a generally rare but important contribution to understanding sea-level oscillations during the late Quaternary. Most of these data originate from speleothems recovered in caves that are presently submerged by seawater but can provide direct evidence for periods of time when the cave was either emergent (above sea level), situated coincident with the sea surface, or submerged. In particular, the timing of speleothem growth, phreatic overgrowths, or biogenic encrustations have all been employed to infer periods of time when the cave was above, at, or below local sea level, respectively.

During recent glacial–interglacial cycles, direct observational evidence of sea-level position and timing rests largely on radiometric dates of sedimentary materials that have a definable relationship to the sea surface. In particular, U-series dating of fossil corals that grew near the sea surface have been instrumental in defining the timing and structure of past sea-level change (Edwards et al., 1987, 2003). The sea-level archive contained in submerged speleothems is complementary to that of corals in two significant ways. First, porous, aragonite coral skeletons are susceptible to alteration with time; hence, the utility of this record rapidly degrades prior to the last full glacial cycle. Fortunately, dense spelean calcite is much more resistant to alteration and can more readily be applied to the full-time range accessible by U-series dating (Richards and Dorale, 2003). Second, corals grow at or near the sea surface and therefore provide a minimum estimate of sea-level position. In contrast, speleothems grow in caves above sea level and hence provide an upper bound to sea surface elevation, which helps to bracket the position of sea level when combined with coral data.

The additional value of the submerged speleothem record is that it has the potential to shed light on sea level across the full range of elevations experienced by sea level during the late Quaternary, to the degree that these are represented in sample collections. For purposes of constructing comprehensive sea-level curves, data from glacial periods are essential as glacials dominate the Pleistocene; they comprise about 90% of the time relative to the shorter-lived interglacials. Unfortunately, there is little direct observational evidence for sea-level position during glacial periods because of the difficulty entailed in recovering samples (such as corals or speleothems) that remain submerged by seawater. Hence, the limited submerged speleothem archive has served as a valuable window into the reconstruction of sea-level lowstands, the details of which are generally less well known than their counterpart highstands that are better expressed in the sedimentary record, physically more accessible, and correspondingly better constrained in terms of both elevation and radiometric age.

Sea-level observations from cave data also provide critical benchmarks to test against other sea-level reconstructions. For glacial–interglacial cycles prior to the inception of the last

interglacial sea-level highstand (128 ka; Stirling et al., 1998), sea-level curves are primarily based on the chemical composition of carbonate shells of benthic Foraminifera that reflect the combined influence of ice volume and temperature. Compilations of benthic oxygen isotope ($\delta^{18}\text{O}$) data are often used to infer sea-level variability and corresponding volumes of grounded ice despite the recognition that the relative contributions of the ice volume and water temperature components to this signal are uncertain in terms of both magnitude and timing and that the relationship between these components may not behave in a consistent, predictable manner over multiple glacial–interglacial cycles (e.g., Chappell and Shackleton, 1986; Lisiecki and Raymo, 2005). In light of this, several different approaches have been taken to attempt to strip out the ice volume signal using combinations of proxies or modeling-based reconstructions (Bintanja et al., 2005; Lea et al., 2002; Siddall et al., 2003; Waelbroeck et al., 2002). These sea-level reconstructions can differ from each other significantly and hence, it is critical to provide benchmarks of direct observational evidence for sea level that are well constrained in terms of both elevation and time to test existing sea-level models and reconstructions. Cave data can be employed to test these reconstructions, particularly beyond the last full glacial cycle when well-dated, direct observational evidence of sea-level position becomes increasingly scarce.

Of course cave data, like other archives of sea-level data, must be considered in the context of past and present changes in the Earth's surface that result from glacio-hydro-isostasy. Variations in the loading of volumes of ice and water on Earth's surface on glacial–interglacial timescales impart a signal on sea-level observations – whether they be historical tide gauge measurements, Holocene or Quaternary sea-level data, or paleoshorelines that were formed deeper in geologic time. Even cave data from localities that are generally considered stable platforms may have relative sea-level histories that depart significantly from the global, or eustatic, sea-level curve (Farrell and Clark, 1976) depending, in part, on their distance from former ice sheet margins and, on longer timescales relating to dynamic topography of mantle flow (Moucha et al., 2008). The influence of glacio-hydro-isostasy is particularly relevant for the submerged speleothem record and for biogenic and phreatic overgrowths on speleothems, which have been dominantly reported in two regions (the Bahamas and Mediterranean) that have both been situated on peripheral bulges of former land-based ice sheets in the Northern Hemisphere.

Speleothem Growth: Providing Upper Bounds on Sea-Level Position

Presently submerged caves as well as some emergent caves may contain speleothems – stalagmites, stalactites, or flowstones – some of which may display hiatuses formed during seawater incursions into the cave. Such specimens provide rare and

informative markers of relative sea level. Using precise and accurate U-series dating techniques to establish the age of the spelean calcite defines the period of time when the cave was positioned above the sea surface. While all speleothems must have formed at some elevation above sea level, specimens with growth interruptions related to cave flooding by seawater can be used to establish the timing of sea-level oscillations by dating spelean carbonate on either side of the hiatus marking submarine conditions. These hiatuses are sometimes marked by dissolution features, Fe-rich flocculates or sediment layers, or seawater evaporates such as halite and gypsum (Antonioli et al., 2004; Dutton et al., 2009a; Li et al., 1989; Suric et al., 2009). In rare circumstances, biogenic crusts such as serpulid calcite (worm tubes) encase speleothems during marine submergence and can be preserved within the hiatus of speleothem growth (Antonioli et al., 2004; Bard et al., 2002; Dutton et al., 2009a). Several specimens from the Bahamas and the Mediterranean, including those that contain hiatuses due to sea-level transgressions, have been examined in this manner, and provide important constraints for sea-level oscillations over the last two glacial–interglacial cycles (e.g., Bard et al., 2002; Dutton et al., 2009a; Harmon et al., 1983; Li et al., 1989; Lundberg and Ford, 1994; Richards et al., 1994; Spalding and Mathews, 1972; Suric et al., 2009).

Submerged speleothems (predominantly stalagmites and flowstones) were first exploited as an archive of sea-level change using U-series alpha-dating techniques for specimens recovered in the Bahamas and Bermuda (Gascoyne, 1984; Gascoyne et al., 1979; Harmon et al., 1981, 1983; Spalding and Mathews, 1972). These studies included specimens from up to 16 m above sea level and submerged samples extending down to –20 m. Improvements in precision offered by mass spectrometry allowed for more precise determinations of previous sea-level highstands in the Bahamas based on a submerged flowstone (DWBAH) (Li et al., 1989; Lundberg and Ford, 1994) extending back to marine isotope stage (MIS) 8 (~275 ka). There remains some uncertainty around the accuracy of dates from this flowstone, because this region can have unusual compositions of detrital thorium (Richards and Dorale, 2003). The assumption that is made regarding the composition of the detrital thorium can change the ages significantly (by ~13 ka in one sample from the DWBAH flowstone). However, the number of hiatuses preserved in this flowstone still provides valuable insight into the relative elevation of various sea-level highstands in the past.

Sample collections extending over a range of depths (0 to –60 m) from blue holes in the Bahamas further defined periods of cave emergence and submergence during the last and penultimate glacial period (Richards et al., 1994; Smart et al., 1998; Figure 1). Richards et al. (1994) noted that the submerged speleothem data displayed a structure of gradually lower sea levels approaching the glacial maximum followed by rapid recovery of sea level during the deglaciation that mimicked the pattern long observed in marine oxygen isotope record (Emiliani, 1955). Moreover, Richards et al. (1994) recognized that speleothem growth ceased in some samples even before rising sea levels could have interrupted their growth, implicating another mechanism controlling speleothem growth rates such as reduction of groundwater recharge due to aridity.

Hiatuses observed in submerged stalagmites recovered from various sites along the Mediterranean coastline have also been dated to reconstruct past sea-level oscillations, particularly the sea-level highstands associated with MIS 5 and 7 (Bard et al., 2002; Dutton et al., 2009a; Suric et al., 2009). The work along the Italian coastline in Argentarola Cave (Bard et al., 2002; Dutton et al., 2009a) is notable for providing important constraints on the timing of sea-level highstands during MIS 7, a period of time that has far fewer radiometric ages to constrain sea-level oscillations than those of the last glacial cycle (Figure 2). This work also combined data from specimens across a limited depth range of a few meters, and recognized a different number of highstands recorded in different stalagmites that was used to interpret the elevation of sea-level position during MIS 7.3 (Dutton et al., 2009a). This observation in particular proved useful in testing various reconstructions of sea level during MIS 7 derived from marine cores or models that differed significantly in terms of the relative elevations predicted for the MIS 7 sea-level highstands.

Suric et al. (2009) dated the timing of hiatuses preserved in a submerged stalagmite from Croatia to interpret a double peak in sea level for MIS 5a. This observation provides corroboration for evidence of such a double peak observed at coral-based sea-level reconstruction from Barbados (Potter et al., 2004; Schellmann and Radtke, 2004). Because relative sea-level records can be influenced by local effects such as tectonic or isostatic effects, the establishment of sea-level oscillations such as those during MIS 5a should be recognized as a globally distributed feature before invoking a eustatic origin to the signal, making the discovery of this double peak in Croatia as well as in Barbados particularly important.

Where tectonic movement is a factor, submerged speleothem data can also be invoked in a different manner. Provided a reasonable eustatic sea-level (and ice sheet) history in combination with glacio-hydro-isostatic modeling to characterize the relative sea-level signal, the timing of speleothem growth at different elevations along a tectonically active coastline can be used to constrain the rate of vertical movement. This approach was used to define a range of reasonable uplift rates for the Sicilian coastline, whereby the timing of speleothem growth was limited to the area above the sea-level curve (Dutton et al., 2009b; Figure 3). Suric et al. (2009) also make a similar comparison with their MIS 5a data to constrain uplift rates along the Adriatic coast, but in this case the comparison was made to a eustatic sea-level curve (Lambeck and Chappell, 2001) rather than a model-derived prediction for relative sea level.

In all cases where spelean calcite has been dated to establish the timing of cave emergence, these ages provide minimum estimates of the period of time that the cave was above sea level. Speleothem growth may terminate before sea-level rise due to changing climatic conditions (Bard et al., 2002; Richards et al., 1994) or changes in cave hydrology and it is also not clear how long it takes after sea level has dropped for speleothem growth to resume. In some cases this uncertainty may be within the error of the age determination, but in other instances the delay may be more significant. Despite long periods of seawater submergence, many speleothems show no evidence of dissolution, but in other cases there is some evidence of dissolution that has been attributed to

Figure 1 Sea-level data from speleothems in Bahama 'blue holes.' Constrained age/elevation sea-level curve based on speleothems from the Bahamas. (Sea-level elevation defined as distance below present sea-level.) (a) Horizontal bars represent single ages (arrows associated with bars indicate whether top or basal age only), or periods of continuous growth extrapolated from basal and top ages. Both α -spectrometric (white bars) and mass-spectrometric analyses (black bars, and gray bar from Li et al. (1989)) are shown. These bars constrain (± 0.1 m) the upper limit of sea-level elevations to within the shaded portion of the figure (subsidence rates are not taken into account). For comparison, estimates of age and elevation for high sea-stands, based on ^{230}Th ages of coral reef terraces are illustrated: Huon Peninsula terraces II–VI (Aharon and Chappell, 1986) (heavy boxes) and Barbados (Bard et al., 1990; Gallup et al., 1994) (light boxes). The postglacial sea-level curve is shown to highlight the cessation of speleothem growth before inundation by rising sea levels. (b) Comparison with inferred record of ice volume from $\delta^{18}\text{O}$ of benthic Foraminifera from the Norwegian Sea (Labeyrie et al., 1987) and low sea-stands based on deltaic gravels from the Huon Peninsula (Chappell and Shackleton, 1986) (V) and dated corals below subaerial surface exposures, Barbados (light boxes). Periods of time represented by hiatuses in growth for several speleothems denoted by dashed lines. Modified from Richards DA, Smart PL, and Edwards RL (1994) Maximum sea levels for the last glacial period from U-series ages of submerged speleothems. *Nature* 367: 357–360, with permission.

calcite-undersaturated waters of the mixing zone between fresh water and seawater (Dutton et al., 2009a; Richards and Dorale, 2003).

Marine Submergence: Providing Lower Bounds on Sea-Level Position

Organisms that encrust or bore into submerged speleothems when caves become inundated with seawater can also be dated to establish a minimum age for cave flooding. Antonioli and Oliverio (1996) established the radiocarbon age of a mussel that had bored into a submerged speleothem

recovered from -48 m relative to present mean sea level in Palinuro Cave along the west coast of Italy. The age of the mussel represents a minimum estimate for the timing of cave flooding during the last deglaciation. Serpulid calcite crusts on submerged speleothems have also been ^{14}C dated to determine the timing of cave flooding in Palinuro Cave, Argentarola Cave, and near Siracusa, Italy (Antonioli et al., 2001; Dutton et al., 2009b). The timing of cave inundation has been compared in both studies to relative sea-level curves derived from glacio-hydro-isostatic modeling, which show good agreement with the radiocarbon ages. These ages provide important benchmarks to test the models of relative sea-level change in this region.

Figure 2 Summary of MIS 7 sea-level highstands with constraints from submerged stalagmites recovered at -18 to -21.5 m below sea level in Argentarola Cave, Italy. Submerged stalagmite U-series data represent growth periods and should be above the sea-level curve. Solid lines connecting speleothem U-series ages represent periods of continuous growth. The error bars for samples next to hiatuses are shown as dashed lines. Peak MIS 7.5 coral data were assumed to sit at modern sea level. Modified from Dutton A, Bard E, Antonioli F, Esat TM, Lambeck K, and McCulloch MT (2009) Phasing and amplitude of sea-level and climate change during the penultimate interglacial. *Nature Geoscience* 2: 355–359, with permission.

Figure 3 Submerged speleothem data from Sicily to constrain uplift history. U-series and ^{14}C data are plotted with several uplift scenarios for the Siracusa coastline. In many cases, error bars are not visible because the errors are smaller than the size of the symbol. Open symbols represent U-series ages of speleothem calcite growth and hence should sit above the sea-level curve. Solid symbols are ^{14}C ages of serpulid calcite and should be below the sea-level curve as they represent time periods of cave submergence. Scenarios where the open symbols sit below the sea-level curve are not plausible uplift histories. Uplift rates between 0.20 and 0.40 mm a^{-1} appear to be in best agreement with the speleothem data. Reproduced from Dutton A, Scicchitano G, Monaco C, et al. (2009) Uplift rates defined by U-series and ^{14}C ages of serpulid-encrusted speleothems from submerged caves near Siracusa, Sicily (Italy). *Quaternary Geochronology* 4: 2–10, with permission.

Phreatic Overgrowths: Tracking Sea-Level Position

A more unusual, but extremely informative type of cave deposit that has been used to establish the timing and magnitude of sea-level changes is phreatic overgrowths on speleothems, sometimes referred to as POS. These have been described for caves in Mallorca, where encrustations of calcite or aragonite coat the surface of speleothems and cave walls at the air–water interface (Pomar et al., 1979). The overgrowths occur within the range of tides and are thickest at the mean position of sea level (Figure 4). The core speleothem (stalagmite or stalactite) will have an older age compared to the encrustation, which can be dated itself to establish the timing of sea level still stands that appear to be recorded across a wide range of elevations within these cave systems, from +46 to –23 m above and below mean sea level (Gines et al., 2003). Slight variations in elevations of cogenetic phreatic overgrowths along the laterally extensive cave system of the southeast coastline of Mallorca have also been used to establish the rate of tectonic tilting in the region (Fornós et al., 2002).

Up to 30 paleo levels of phreatic speleothems have been recognized in Mallorca (Gines et al., 2003). This archive clearly has the potential to deliver a detailed history of sea-level positions over recent glacial–interglacial cycles. Mass-spectrometric U-series data for these phreatic overgrowths has largely focused on those formed during the

entirety of MIS 5 (Dorale et al., 2010; Gines et al., 2003; Tuccimei et al., 2006), including both the sea-level highstands as well as the lowstands. Interestingly, the elevations of MIS 5a, 5c, and 5e all appear to be similar (+1 to +3 m above present mean sea level) (Gines et al., 2003). The significance of these elevations in terms of global grounded ice volume is not entirely clear in the absence of glacio-hydro-isostatic modeling to understand the relation between relative sea level at Mallorca and the eustatic sea-level history. Even if Mallorca may be currently undergoing only slow vertical movement in response to ongoing relaxation of the Earth's surface to the Last Glacial Maximum (Dorale et al., 2010), because the elevations of these former sea-level highstands are also a function of the ice history preceding the highstand, the difference between present sea level and the elevation of a past sea-level highstand cannot be directly equated to ice volume (Lambeck et al., 2012). This is a generalization that holds true for other sites outside of Mallorca as well, and is important in the context of all of the cave data discussed here.

Additional Considerations

In all cave environments there may be other factors than sea level that can affect the timing of hiatuses in speleothems.

Figure 4 Schematic diagram of littoral karst in Mallorca outlined in an ideal cross-section. Note presence of phreatic overgrowths related to past and present sea levels, as well as the detailed morphology due to the tidal and atmospheric oscillation of the coastal water table. Reproduced from Fornós JJ, Gelabert B, Gines A, Gines J, Tuccimei P, and Vesica P (2002) Phreatic overgrowths on speleothems: A useful tool in structural geology in littoral karstic landscapes. The example of eastern Mallorca (Balearic Islands). *Geodinamica Acta* 15: 113–125, with permission.

Hiatuses can develop in subaerial caves far from the coasts due to changes in precipitation, groundwater recharge, and cave hydrology. For this reason, it is important to establish a line of evidence that indicates that a hiatus was formed due to the incursion of seawater; for example, trace amounts of seawater evaporates (Suric et al., 2009), serpulid crusts (Antonioli et al., 2004; Bard et al., 2002; Dutton et al., 2009a), or Fe-rich flocculates (Li et al., 1989) have all been interpreted to indicate the presence of seawater in the cave.

To serve as an accurate recorder of sea-level position, the cave must be situated along the coastline, for example, a flank margin cave (Myroie and Carew, 2006), because cave systems that extend inland may also be flooded, but the elevations of the fresh water lens and the seawater/freshwater interface will be a function of distance from the coastline and will not be at the same elevation as sea level along the coast. Therefore, for the purposes of reconstructing sea-level position, it is important to focus on caves that were immediately adjacent to the coastline during the time period of interest.

Finally, there remains the issue of how best to interpret radiometric ages and associated elevations of the various cave deposits discussed here given that each site will have a relative sea-level history that may be different from the eustatic sea-level curve (Farrell and Clark, 1976). Particularly in the Bahamas, Bermuda, and the Mediterranean, where many of these studies have been conducted, nearby ice sheets as well as water loading effects are expected to cause significant departures of relative sea level from the eustatic signal (Lambeck and Purcell, 2005; Potter and Lambeck, 2003). There are essentially two effective approaches to handling this: (1) discuss the cave data in the context of a full glacio-hydro-isostatic model in cases where an ice model covering the time interval from before the period of interest up to the present; or (2) understand the limitations of the data and make appropriate interpretations without dismissing the unquantified gravitational and rotational effects related to glacio-hydro-isostasy. For example, if the first scenario is not possible, then one appropriate and meaningful comparison would be to compare the timing of speleothem growth with that of nearby coral growth to understand the timing of sea-level change, and possible time lags between the two archives. Also, simply quantifying the number of sea-level oscillations within a certain time span can provide important information (e.g., Suric et al., 2009). If the age data in question falls during a deglacial event where rates of sea-level change are fast, on the order of ~ 10 m/1000 years, then it is possible that any uncertainty in elevation due to isostatic effects is already accounted for in the analytical error of the age (e.g., Dutton et al., 2009a), particularly in the case of older samples that may have larger error bars associated with measured U-series ages. In this case, the error envelope on the age spans a sufficient period of time during which sea level changed rapidly and will contribute a larger uncertainty than the isostatic correction to the relative sea-level data.

Conclusions

Radiometric dates of stalagmites, stalactites, and flowstones are a valuable tool to establish upper limits of sea-level position through time. Establishing the timing of speleothem growth helps to set bounds on the timing of cave emergence above sea

level. Dates bounding erosional unconformities in speleothems formed during seawater submergence provide further constraints on the timing of sea-level highstands and the elevation of the speleothem in the cave provides an important limit on the position of sea level at that time. Organisms that encrust or bore into cave deposits can be studied to provide a complementary age on the timing of cave submergence. In particular environments, it is also possible to capitalize on the occurrence of phreatic overgrowths that form at the sea surface to establish the timing and position of sea level. In this last case, instead of providing a bracketing age, that is an age that represents a minimum or maximum estimate on the timing of sea level passing through the elevation of the cave, the age of the phreatic overgrowth represents the exact time at which sea level was at that position. In all cases, these age constraints provide important benchmarks to test existing models and reconstructions of sea level through time.

Our understanding of the timing and magnitude of sea-level changes can be greatly enhanced by further study of both emergent and submerged caves. In particular, submerged caves have the potential to deliver rare information on the timing of sea-level lowstands, and the timing of sea-level changes during glacial periods in addition to providing bracketing ages for sea-level highstands. Existing data from submerged speleothems and associated cave deposits are scarce due to practical difficulties entailed in locating and recovering samples from underwater caves. In fact, this raises an ethical question of how this line of research should be pursued in light of the risk involved with cave diving to collect these valuable specimens. Perhaps there is scope to conduct future explorations or even sampling of submerged cave systems with remotely operated underwater vehicles.

Alternatively, one could also turn to uplifted areas to access speleothems in caves that were once submerged. Coral terraces exposed by rapid tectonic uplift have been exploited to access this portion of the record at localities such as Barbados and Huon Peninsula, Papua New Guinea (Chappell and Polach, 1991; Fairbanks, 1989). Unfortunately, there remain few examples of radiometrically dated speleothems from similarly uplifted environments to constrain former sea-level oscillations. Cave exploration in such environments certainly has the potential to yield an important and largely untapped resource for additional constraints on past sea-level change.

Introduction

The distribution of glaciers and ice sheets on the Earth's surface today is overwhelmingly concentrated in the high latitudes. During the Late Quaternary, however, ice cover in these areas was even more extensive and ice sheets expanded across continental shelves, depressing the Earth's crust and delivering sediment to the deep ocean basins (Clark and Mix, 2002). Relative sea-level (RSL) histories from these high-latitude regions preserve a record of the nature and pattern of crustal rebound following ice-sheet decay and can be used to construct isobases from which the location of former ice-sheet loading centers can be determined. The aim of this encyclopedia entry is to outline the controls on, and nature of, Late Quaternary RSL change in the high latitudes. These concepts are illustrated by case studies of Late Quaternary RSL change: the first from the Queen Elizabeth Islands (QEI) of the Canadian High Arctic and the second from Antarctica, which discusses a series of RSL records from around the continent. The focus of this entry is predominantly on observational studies of near-field RSL histories; far-field components (cf. Bassett et al., 2005) are not dealt with in detail here.

RSL Change in High Latitudes: Controls and Patterns

The RSL history of a given site is influenced by a combination of eustatic, isostatic, hydroisostatic and tectonic influences. The dominance of eustasy versus isostasy depends on the location of the site with respect to the former ice-sheet loading center. Within former ice-sheet limits ('near-field sites'), RSL history is dominated by the isostatic component and records crustal rebound following ice-sheet decay. Far from the ice-sheet margin ('far-field sites'), the RSL history is dominated by eustatic factors.

Clark et al. (1978) present a classic model which divides the globe into a series of zones based on the characteristics of their RSL curves (Figure 1) (note that later models and data show variants on this). The high latitudes are characterized by glacioisostatically dominated, Late Quaternary RSL histories due to the former presence of ice sheets in these regions. Zone I comprises those areas within the former ice-sheet margin that have experienced continuous, exponential RSL fall since deglaciation, with the magnitude of emergence reflecting the proximity to the ice-sheet loading center. Zone II is characterized by continuous submergence due to the presence of the collapsing proglacial forebulge which, following deglaciation, migrates toward the former ice-sheet center with time. The forebulge is formed of sublithospheric material extruded from beneath the growing ice sheet as it isostatically depresses the crust. During deglaciation, the ice sheet retreats and the resulting isostatic disequilibrium causes this material to flow back toward the former ice-sheet center. Regions near the former ice-sheet margin experience RSL changes that are transitional between Zones I and II. At the ice-sheet margin there is initial emergence followed by later submergence as the forebulge migrates (Figure 2). The relative magnitude of submergence versus emergence depends on the position of a site with respect to the former loading center; greater submergence occurs with increasing distance from the ice sheet and submergence commences at a later time for sites close to the ice sheet than for sites at a greater distance.

In the case of the last North American (Laurentide) ice sheet, the time-transgressive nature of its retreat meant that the forebulge migrated back through Atlantic Canada following the retreating ice edge (Quinlan and Beaumont, 1981). Quinlan and Beaumont (1981) have shown the effect of forebulge migration on RSL history (Figure 2). Sites A, B and C are all on the leading edge of the forebulge. These sites all experience emergence/RSL fall as the bulge crest approaches, and submergence/RSL rise as the bulge crest passes. Site D is

Figure 1 (a) Distribution of sea-level zones and (b) RSL curves typical of each zone. Modified from Clark JA, Farrell WE, and Peltier WR (1978) Global changes in postglacial sea level: A numerical calculation. *Quaternary Research* 9: 265–287.

located beyond the maximum position of the crest and experiences only subsidence/RSL rise. Thus RSL falls continuously at site A with the bulge crest yet to pass this point. At sites B and C there is an initial period of RSL fall as the crest approaches, followed by RSL rise as the crest passes. However, the duration of RSL rise and fall is different for these sites. At site D there is only RSL rise. Sites A and D correspond to Zones I and II of Clark et al. (1978) while sites C and D correspond to the transitional Zone I/II.

The maximum elevation attained by the sea along a glacioisostatically depressed coastline is referred to as the 'marine limit.' Following the seminal pioneering work on the postglacial RSL history of the Canadian Arctic by Andrews

(1970), the elevation of marine limit and form of the subsequent RSL curve are recognized as being a function of distance from the former ice-sheet margin (which is an indication of ice thickness over the site), date of deglaciation and eustatic sea-level rise. In areas that were formerly glacier covered, marine limit is formed time transgressively as the ice sheet retreats. In the Arctic and Antarctica, marine limit is generally defined by a range of criteria: (1) the elevation of the highest raised beach or delta terrace; (2) the lowest elevation of undisturbed till, delicately poised erratic boulders, or felsenmeer (washing limits); and (3) the highest elevation at which marine shells or the remains of marine mammals can be found. These criteria generally provide a minimum estimate for marine limit

Figure 2 (a) Schematic representation of a peripheral forebulge at two points in time, 18 ka BP and the present day. The forebulge migrates in the direction of ice-sheet retreat thereby affecting RSL at the four sites A, B, C, and D. (b) RSL curves from sites A–D recording the forebulge migration shown in panel A. Modified from [Quinlan G and Beaumont C \(1981\)](#) A comparison of observed and theoretical postglacial relative sea level in Atlantic Canada. *Canadian Journal of Earth Sciences* 18: 1146–1163. The vertical scale on the four RSL curves indicates the nature of the RSL change rather than the precise magnitude of this change, as the latter will differ depending upon a range of variables including ice-sheet thickness, deglacial history, and ice-sheet volume.

elevation. The age of marine limit (and thus the timing of initial deglaciation) is generally constrained through radiocarbon dating of a variety of associated organic material: marine shells in growth position within delta bottomset beds that can be related to the marine limit delta terrace; buried driftwood or whalebone in raised beach ridges; and surface shells on raised beaches or delta foreslopes (these give a minimum estimate on the age of marine limit as they could have been moved downslope subsequent to marine limit formation). In addition, dating of the transition from marine sediment to organic lacustrine material in cores recovered from isolation basins close to marine limit also provide chronological constraints on the formation of marine limit and the timing of deglaciation (e.g., [Bentley et al., 2005](#); [Long et al., 1999](#)).

Marine limit is not a synchronous shoreline and its elevation over an area does not represent the time-dependent form of glacioisostatic rebound. For this, measurement of synchronous shorelines must be made. Such shorelines slope up toward the ice-sheet center because they have been uplifted by differing amounts depending on their proximity to the former loading center. The tilt of such synchronous shorelines can be represented by isobases (contour lines joining points of equal uplift over an equal amount of time). Younger shorelines tend to be tilted less steeply than older shorelines due to the decrease in differential uplift over time.

Case Studies of Late Quaternary RSL Change in High Latitudes

QEI, Canadian High Arctic

The QEI of the Canadian High Arctic are located north of the Parry Channel ([Figure 3](#)) and comprise a geologically and

physiographically complex archipelago. The greatest relief occurs in the fretted mountains of northern and eastern Ellesmere Island, eastern Devon Island, and central Axel Heiberg Island. The smaller islands of the central and western parts of the archipelago are characterized by lowland and plain topography. Modern glacier cover is largely restricted to ice caps and outlet glaciers on Ellesmere and Devon islands with only small, scattered ice masses in the rest of the archipelago.

[Blake \(1970\)](#) first proposed the existence of the Innuitian Ice Sheet over the QEI during the last glaciation (marine isotope stage 2) based mainly on the pattern of differential postglacial rebound since 5 ka BP. He demonstrated that shorelines of this age were highest throughout a broad corridor oriented northeast–southwest extending from northern Eureka Sound to Bathurst Island. This ridge of high Holocene emergence was termed the Innuitian Uplift by [Walcott \(1972\)](#). Blake proposed that this emergence reflected the removal of a regional ice sheet which covered the QEI during the Last Glacial Maximum (LGM), whose axis of maximum thickness corresponded to the corridor of maximum uplift. The Innuitian Ice Sheet was coalescent with the Greenland Ice Sheet to the east and the Laurentide Ice Sheet to the south. In contrast, a markedly different reconstruction of the glacial history was proposed by [England \(1976, 1983\)](#) who argued that the last glaciation was very restricted and that outlet glaciers only advanced a few tens of kilometers beyond their present margins. This alternative interpretation was based on an apparent absence of primary glacial geological evidence for an Innuitian Ice Sheet, evidence that the only extensive glaciation in the QEI predated the LGM, and RSL evidence that the fjords and interisland channels of the eastern QEI were occupied by a full-glacial sea during the last glaciation. These contrasting reconstructions formed the end members in an ensuing debate over glacial

Figure 3 Schematic map of the paleogeography of the Innuitian Ice Sheet, Queen Elizabeth Islands, Canadian High Arctic, at the Last Glacial Maximum (modified from England J, Atkinson N, Bednarski J, Dyke AS, Hodgson DA, and Ó Cofaigh C (2006) The Innuitian Ice Sheet: Configuration, dynamics and chronology. *Quaternary Science Reviews* 25: 689–703). The Innuitian Ice Sheet was coalescent with the Greenland Ice Sheet to the east and the Laurentide Ice Sheet to the south. Primary ice divides in the alpine sector of the ice sheet (thick black lines) are termed the Ellesmere Divide (ED) and Lowland Divide (LD). Adjoining secondary divides (thinner black lines) extend from primary divides and generate areas of strong flow convergence that are recorded by glacial geological and geomorphological evidence.

extent during the LGM in the QEI which lasted over two decades. More recent investigations have rejected evidence for a full-glacial sea and the supposed antiquity of regional glaciation and have reconciled the pattern of postglacial emergence in the QEI with geological evidence for extensive ice cover at the LGM, thereby providing consensus for an Innuitian Ice Sheet (e.g., Atkinson, 2003; Atkinson and England, 2004; Dyke, 1998, 1999; England, 1998, 1999; England et al., 2006; Ó Cofaigh, 1999; Ó Cofaigh et al., 2000). We briefly summarize the salient features of the ice-sheet history here and detail the pattern and form of postglacial rebound associated with removal of the ice load upon deglaciation (see England et al., 2006).

Radiocarbon dates on subfossil organics and ice transported marine shells in till provide maximum ages for the build-up of the Innuitian Ice Sheet. They indicate that the ice sheet developed about 23–19 ka BP. During build-up, ice from eastern Ellesmere Island advanced into fjords and interisland

channels, forming trunk ice at least 1000 m thick. Ice flow from a divide situated over central Ellesmere Island flowed west into Eureka Sound (Figure 3) and coalesced with flow from a divide on Axel Heiberg Island, resulting in a 1200-m thick trunk ice in Eureka Sound, which debouched north into Nansen Sound and south into the Norwegian Bay. Ice thickness over the Ellesmere Island ice divide (Figure 3) did not exceed 200 m thicker than the present day thickness and thus the zone of thickest ice, and hence maximum ice-sheet loading, was situated over the intermontane basin of Eureka Sound rather than over the ice sheet divides. The lowland sector of the ice sheet occupied the central and possibly the western sector of the QEI. Ice flow from an east–west orientated divide in the Norwegian Bay fed ice southward as well as north to the continental shelf. Deglaciation was underway by at least 11.6 ka BP, and by 10 ka BP the ice sheet had started to break up with prominent marine embayments extending into the archipelago from the Arctic Ocean. By 8.5 ka BP, the sea had

penetrated the former ice-sheet center in Eureka Sound and the ice sheet had broken up into a series of residual island ice caps.

The pattern and form of Holocene RSL change in the QEI associated with rebound following deglaciation of the Innuitian Ice Sheet has been well documented through successive field investigations involving surveying and radiocarbon dating of raised marine landforms such as raised marine deltas, beaches, and washing limits (Figure 4). Radiocarbon dates on samples of *in situ* marine shells in growth position, buried driftwood, and whalebone (Figure 4(f)), which can be

associated stratigraphically with these former sea levels, provide the chronology of RSL change.

Because the Innuitian Ice Sheet had broken into a series of residual ice caps by about 8.5 ka BP, shorelines of this age are present across the QEI and have been widely surveyed and dated with the result that isobase maps showing the pattern of unloading associated with this shoreline have been completed for much of the QEI (e.g., Atkinson and England, 2004; Dyke, 1998; England, 1992; England et al., 2006; Ó Cofaigh, 1999). The most recent isobase compilation for

Figure 4 (Continued)

Figure 4 (Continued)

Figure 5 Postglacial isobases drawn on the 8.5 ka BP shoreline in the Queen Elizabeth Islands, Canadian Arctic (modified from England J, Atkinson N, Bednarski J, Dyke AS, Hodgson DA, and Ó Cofaigh C (2006) *The Innuitian Ice Sheet: Configuration, dynamics and chronology. Quaternary Science Reviews* 25: 689–703). The isobase pattern records delevelling associated with removal of the Innuitian Ice Sheet following the Last Glacial Maximum. Note the ridge of maximum postglacial emergence (>130 m asl) which encloses Eureka Sound, the location of former maximum ice-sheet thickness (>1 km). The isobases decline southwestward from Eureka Sound and enclose a prominent northeast–southwest orientated ridge (>110 m asl) in the central archipelago. This ridge marks the location of former maximum ice-sheet thickness in the lowland sector of the Innuitian Ice Sheet.

the 8.5 ka BP shoreline is shown in Figure 5. The isobases form a closed cell of maximum emergence (≥ 130 m asl) over Eureka Sound and the axis of the Innuitian Uplift can be seen to extend southwestward into the Norwegian Bay and then

westward (Figure 5). This demonstrates that the zone of maximum ice-sheet loading at the LGM was centered over the intermontane basin of Eureka Sound and corresponds to the zone of maximum ice thickness (~ 1200 m) rather than

its maximum surface elevation, which occurred over the encircling ice divides on Ellesmere and Axel Heiberg islands. In the lower relief terrain of the central QEI, the zone of maximum uplift corresponds to the former lowland ice divide (Dyke, 1999; England et al., 2006). Isobases on the 8.5 ka shoreline descend both northeast and southwest toward the Arctic Ocean and Baffin Bay respectively and record decreasing ice-sheet thickness toward the former margins. Furthermore, the lack of strong deflection in the isobase pattern across the marine channels of the western part of the QEI suggests that ice-sheet thickness was relatively uniform on, and between, neighboring islands. The pattern of the Innuitian Uplift is asymmetric, with a steeper gradient across the western islands than across those which face Baffin Bay (Figure 5). This may reflect a combination of earlier and more extensive deglaciation of the northwestern QEI, or the proximity of the

southeast QEI to Baffin Bay, which may have facilitated rates of snow accumulation and the generation and maintenance of greater ice thickness (England et al., 2006).

The highest Holocene marine limits in the QEI are found along the coastline of Eureka Sound, where shorelines at 158 m asl are present at the northern end of the channel. Marine limit falls southward down the channel but is still 140 m asl at its southern end. These high marine limits are consistent with the zone of maximum unloading along Eureka Sound as recorded by the pattern of shoreline delevelling drawn on the 8.5 ka BP shoreline (Figure 5; see above). In the eastern and central QEI, in those areas of the archipelago formerly covered by the ice sheet, RSL curves exhibit continuous exponential Holocene RSL fall from marine limit to the present (Blake, 1975; Dyke, 1998; Ó Cofaigh, 1999; Figure 6). The emergence history is thus similar to that of other areas of

Figure 6 RSL curves for sites on Devon Island that were deglaciated by the Late Quaternary Innuitian Ice Sheet. Sites (a–e) show continuous exponential emergence and RSL fall since deglaciation and the formation of marine limit. Site (f) was located closer to the former margin of the Innuitian Ice Sheet and shows initial emergence and RSL fall followed by a period of submergence and RSL rise to the present day. Figure 8 (Continued)

eastern Arctic Canada formerly covered by the Laurentide Ice Sheet (Andrews, 1970) and is consistent with 'Type-A curves' of Quinlan and Beaumont (1981) and the RSL history of sites located within Zone 1 of Clark et al. (1978) (Figures 1 and 2). RSL curves from the northern part of the QEI (Ellef Ringnes and Amund Ringnes islands), from areas behind the former ice-sheet margin, also show continuous exponential crustal relaxation since deglaciation (Atkinson and England, 2004). However, RSL curves from areas close to the ice-sheet margin have a more complex history that comprises an initial period of emergence followed by a late Holocene transgression (Figure 6 (f); Atkinson and England, 2004; Dyke, 1998). On the western islands of the archipelago close to or immediately beyond the ice-sheet limit, there is evidence for a period of late Holocene sea-level rise or a stillstand following RSL fall (Hodgson et al., 1994). The RSL curves toward the former ice-sheet margins and beyond therefore show an initial phase of exponential emergence followed by RSL rise during the Holocene. In some cases, this submergence may be ongoing. The curves from these areas are thus characteristic of 'Type B' RSL curves (Quinlan and Beaumont, 1981) and the Zone I/II transition of Clark et al. (1978) (Figures 1 and 2).

Antarctica

In contrast to the Arctic as illustrated by the case study from the QEI, the development of RSL data from Antarctica is far less comprehensive and is predominantly based on a relatively small number of sites (Figure 7). This is due to several reasons: a large proportion of the coast (>95%) is fronted by glacier ice or ice shelves and so there are few sites where RSL change is recorded; there are logistical difficulties and expense in reaching remote coastal sites; there are difficulties with dating the evidence because of the paucity of organic material. The latter problem is gradually being overcome with the development of innovative ways of dating raised beaches (Figure 8) but the problem of finding suitable sites remains the most intractable and for several sectors of the Antarctic coastline there is little prospect of good quality RSL data.

Most Antarctic RSL data come from one of three regions (Figure 7): (i) the Ross Sea sector, (ii) East Antarctic coastal ice-free areas ('oases'), particularly 75–105° E, and 30–45° E, and (iii) the Antarctic Peninsula. There are very few data for other parts of the Antarctic continent, although RSL studies have been carried out on a number of sub-Antarctic islands.

The Ross Sea arguably has the best quality RSL data in Antarctica. Well-dated RSL curves have recently been developed from the Scott Coast, along the west side of the Ross Sea embayment (Figure 9; Baroni and Hall, 2004; Hall and Denton, 1999; Hall et al., 2004). The development of RSL curves in the Ross Sea region has been aided by innovative approaches to material for radiocarbon dating. While material similar to that used in the Arctic (e.g., *in situ* marine shells) is sometimes found, this is not usually abundant enough to constrain RSL curves in the Antarctic and so other organic material has also been used. For example, subfossil remains from former penguin rookeries (guano-rich soils, bones, feathers) have been used to constrain sea level, based on the assumption that sea level must have been lower than the penguin remains (penguins nest above the current storm

Figure 9 RSL curves for the southern Scott Coast of Victoria Land, Antarctica (see Figure 7 for location). The solid line represents the best fit to the data, whereas the dashed line defines the range of possible RSL change. The samples are from a 60-km stretch of coastline that experienced a relatively uniform ice load and RSL curves from the individual sites all overlap. Dates are corrected for a marine reservoir effect of 1300 years and the precision of sample elevations is estimated at 1 m or better for most samples. Modified from Hall BL, Baroni C, and Denton GH (2004) Holocene relative sea-level history of the southern Victoria Land Coast, Antarctica. *Global and Planetary Change* 42: 241–263.

beach). Similarly, skin fragments from hauled-out elephant seals that have been incorporated into beach material have been used to constrain past sea level (Baroni and Hall, 2004).

The Ross Sea curves show exponential RSL fall since deglaciation of the coastline by the retreating West Antarctic Ice Sheet (Conway et al., 1999). Marine limit in the Ross Sea (~30 m) (Figure 9) is substantially lower than in the Arctic (>150 m in the QEI – see above) because much of the isostatic recovery took place as restrained rebound (i.e., was not recorded as raised marine landforms because of ongoing ice cover of the Ross Sea coastline), and because the Antarctic Ice Sheet continues to provide a substantial regional load on the crust whereas, with the exception of Greenland, the Late Quaternary ice sheets over much of the Arctic have now been largely removed. The Scott Coast is unusual in that the orientation of the former ice-sheet grounding line (east–west) was

Figure 10 Relative sea-level history of the Vestfold Hills, East Antarctica (see [Figure 7](#) for location) for the last ~8000 ^{14}C years, based on isolation basin observations (modified from [Zwartz D, Bird M, Stone J, and Lambeck K \(1998\)](#) Holocene sea level and ice-sheet history in the Vestfold Hills, East Antarctica. *Earth and Planetary Science Letters* 155: 131–145). The box symbols 'lacustrine–marine transition' and 'marine–lacustrine transition' represent the ages of lacustrine–marine and marine–lacustrine sediment transitions recorded in cores collected from six lakes, plotted against the elevation of the sill connecting each of the six lake basins to the sea. Core lengths required for dating these transitions varied from ~3–6 cm of organic-rich lacustrine sediment to 10–15 cm of marine sediment.

Figure 11 RSL curve for Marguerite Bay, Antarctic Peninsula (see [Figure 7](#) for location). The curve utilizes data from seven sites spread over an approximately 60 km × 30 km area in the northern part of the bay. The data are plotted with 1-sigma error bars for the ^{14}C ages and +0.2 m for altitudes. The thick solid line shows the approximate fit to the data and the dashed line shows an extrapolation of the RSL curve to the marine limit. The altitude of the marine limit is shown by the dotted line. The y-intercept of the curve is at 2 m asl, which is the altitude of the modern beach in this area. Modified from [Bentley MJ, Hodgson DA, Smith JA, and Cox NJ \(2005\)](#) Relative sea level curves for the South Shetland Islands and Marguerite Bay, Antarctic Peninsula. *Quaternary Science Reviews* 24: 1203–1216.

transverse to the coastline (which runs north–south), and the grounding line retreated south, along the coast. Despite this, the RSL curves for a series of sites along the Scott Coast are nearly identical. This implies that retreat of the ice-sheet grounding line along this coastline was rapid. The RSL curves have been used to show that the West Antarctic Ice Sheet grounding line in the Ross Sea retreated past the southern Scott Coast by 6300–6600 ^{14}C years BP.

In East Antarctica, Zwartz et al. (1998) used data from isolation basins in the Vestfold Hills to constrain former RSL (Figure 10). A series of freshwater–marine and marine–freshwater transitions in lake sediment cores were used to determine an RSL curve for the past 8000 ^{14}C years. The RSL curve is characteristic of near-field sites located close to the margin of a retreating ice sheet. During the early Holocene, the continued regional loading of the crust by the ice sheet (located only a few tens of kilometers away) prevented isostatic recovery from keeping pace with eustatic sea-level rise and so there was a net RSL rise. A subsequent switch to RSL fall occurred in the mid-Holocene when the meltwater contribution of the Northern Hemisphere ice sheets had declined to near-zero, and so the slow isostatic recovery of the East Antarctic coastline dominated (Figure 10). This form of RSL curve corresponds to Zone V of Clark et al. (1978) (Figure 1). The shift from RSL rise to fall is marked by an RSL highstand. In the Vestfold Hills, the mid-Holocene highstand ($\sim 9\text{--}9.5\text{ m}$) was reached at 6200 ^{14}C years BP. Similar isolation basin work has been carried out in other parts of the East Antarctic coast and results show a similar pattern of a mid-Holocene highstand and subsequent RSL fall (e.g., Verleyen et al., 2005). There has also been extensive work on raised beaches in Lutzow-Holm Bay (Figure 7; e.g., Miura et al., 1998) but some of the shells used to underpin the chronology have proved challenging to date (Takada et al., 2003).

In the Antarctic Peninsula region, RSL curves reflect a more complex history. Bentley et al. (2005) reviewed published investigations of isolation basins and raised beaches in the South Shetland Islands and showed that the northernmost part of the Peninsula has an RSL history broadly comparable to that for Vestfold Hills, with strong geomorphological and isolation basin evidence for a mid-Holocene highstand, but whose timing (especially the initial RSL rise) is not yet well constrained.

In contrast, further south in Marguerite Bay, the RSL curve (Figure 11) most likely reflects exponential isostatic decay after removal of a thick grounded ice load that covered the bay during the LGM. This curve is reasonably well constrained by dates on penguin remains from raised beaches (Figure 8) and two isolation basins from about 6500 ^{14}C years BP to the present. Marine limit is defined by the uppermost elevation of raised beaches and is between 41 and 55 m in altitude. The shape of the curve prior to 6500 ^{14}C years BP is not well-constrained chronologically but an exponential shape is assumed on the basis of the regional ice-sheet history, which shows that the former ice margin extended well offshore from the Antarctic Peninsula. Assuming exponential uplift, extrapolation of the curve prior to 6500 ^{14}C years BP back to the regional marine limit at 41 m asl gives an estimate of about 9000 ^{14}C years BP as a minimum for deglaciation of inner Marguerite Bay.

One of the most important applications of existing and new RSL curves from Antarctica is to constrain coupled models of ice-sheet volume change and glacioisostatic adjustment (e.g., Bassett et al., 2007). These models attempt to infer reasonable ice-sheet histories by testing which histories can satisfy the constraints provided by far-field and near-field RSL datasets. At present, such models are not well constrained in Antarctica, compared to other continents, which is hampering efforts to understand the history of the Antarctic ice sheet.

Late Quaternary Sea-Level Changes in Greenland

Overview of the Greenland Ice Sheet

The Greenland Ice Sheet (GrIS) today is ~ 1.7 million km² in area and covers $\sim 80\%$ of the land mass of Greenland. Its maximum thickness is 3367 m, but has an average thickness of 1600 m (Johnsen et al., 2001; Thomas, 2001). The highest surface elevations are in the northern dome (~ 3200 m above sea level) and the southern dome (~ 2850 m above sea level). It is the only Northern Hemisphere ice sheet to have survived the climate warming since the end of the Last Glacial Maximum (LGM) and would contribute up to 7.3 m of globally averaged sea-level rise if it were to melt entirely (Lemke et al., 2007). Studies of relative sea-level (RSL) changes in Greenland record spatial and temporal patterns of glacio-isostatic rebound that provide important information about the size and former history of the GrIS. In particular, there has been a long tradition of using dated shorelines to infer ages of associated moraine deposits, thus providing age constraints on ice margins through time (e.g., Funder and Hansen, 1996; Kelly, 1980; Weidick, 1968, 1996).

In this article, we start by reviewing existing knowledge regarding the Greenland interglacial sea-level history and the types of RSL data used in such reconstructions. Following this, we briefly describe the long-term history of the GrIS from its initiation ~ 3 Ma until the LGM. We then discuss the evidence for RSL changes since the LGM, with a particular focus on southwest Greenland.

RSL Curves and Types of Evidence Found in Greenland During Interglacials

Within and close to the limits of former ice sheets, RSL histories following deglaciation are dominated by glacio-isostasy in the form of crustal rebound following ice sheet decay. In Clark et al. (1978) classic model of zones of RSL change around the globe, Greenland stands between zones I and II. During interglacials Greenland has experienced tens to hundreds of meters of RSL fall following local (Greenland) deglaciation, but it is also affected by forebulge collapse causing subsequent RSL rise. Clark et al. model simplifies the interglacial RSL curve for Greenland because it does not take into account the proximity of the Laurentide ice sheet and its decaying forebulge, or the late Holocene regrowth of the GrIS that happened during the neoglacial period, which followed the mid-Holocene climatic optimum (8–5 k cal yr BP) (Dahl-Jensen et al., 1998; Kelly, 1980). Nevertheless, the Clark et al. (1978) model provides a good indication of typical interglacial RSL changes in Greenland. This shape of curve is often referred to in the literature as a 'J-shaped' RSL curve because of the fall in RSL from above to below present sea level, followed by a late Holocene rise to present (Long et al., 2011; Rasch, 2000).

Evidence for pre-Holocene RSL changes in Greenland is fragmentary (Funder et al., 1991). In east Greenland, raised marine, deltaic, and fluvial sediments from several previous interglacials are preserved in small coastal cliff and river valley sections, notably in the Scoresby Sund area (Funder et al., 1998) (Figure 1(a)). Identifying their age and context can be difficult because sites are widely spaced and each contains only a small part of the overall deglaciation history. Typically, the sequences record sediments associated with a fall in RSL, with progressively shallower water deposits that may be capped with beach deposits as the land finally emerges from the sea. Since the LGM, evidence for RSL changes is much more plentiful. Once the ice margin had retreated on land it is relatively easy to map the height of the local marine limit, which represents the maximum postglacial uplift in that locality. The marine limit is often defined by the lower limit of perched boulders or the upper limit of wave washed bedrock.

After the marine limit has formed, local RSL fall leaves evidence of former marine conditions across the landscape in the form of glacio-marine spreads, raised beaches, and deltas (e.g., Funder, 1989; Funder and Hansen, 1996; Kelly, 1980; Rasch, 2000; Ten Brink and Weidick, 1975; Weidick, 1972). Isolation basins (natural depressions that at different times are either connected to or isolated from the sea by changes in RSL) provide another source of RSL data, useful for tracking millennial-scale RSL change (Long et al., 2011). Researchers are also starting to investigate salt marsh deposits in west Greenland which record small-scale RSL movements over the last few centuries (Long et al., 2010, 2012; Woodroffe and Long, 2009).

Greenland Ice Sheet Through Time

Eocene–Pliocene

During the late Eocene (~ 41 Ma), it is thought Greenland was mostly ice free at a time when glaciation was developing in Antarctica (Edgar et al., 2007). There is evidence that small mountain glaciers were present in east Greenland between ~ 38 and 30 Ma from records of ice-rafted debris in marine sediments from the Norwegian–Greenland sea (Eldrett et al., 2007). However, it was not until much later at the Pliocene/Quaternary boundary (~ 3 –2 Ma) that the Northern Hemisphere entered an 'ice-house' world with extensive glaciation over Greenland (Maslin et al., 1998). Models suggest that during this period the ice sheet grew from a small area in east Greenland to cover most of the land surface, driven by changes in orbital forcing and a decrease in atmospheric CO₂ levels (Lunt et al., 2008). Despite this overall cooling trend, the Kap København and Île de France formations in northern and northeastern Greenland show that climate was mild for at least small periods at this time (Bennike et al., 2002a; Funder

Figure 1 (a) Location map of Greenland showing the locations discussed in the text. (b) Map of the Holocene marine limit from Greenland. Modified from Funder S and Hansen L (1996) The Greenland ice sheet – A model for its culmination and decay during and after the Last Glacial Maximum. *Bulletin of the Geological Society of Denmark* 42: 137–152.

et al., 2001) (Figure 1(a)). The Kap København formation is interpreted as an interglacial marine and then freshwater sequence, deposited under the J-shaped RSL history described above. The formation has yielded plant, insect, and a few vertebrate remains suggesting the presence of local boreal forest with estimated mean temperatures of the warmest month of 10 °C here ~2.4 Ma. Funder et al. (2001) suggest that the rest of Greenland could not have been glaciated at this time if the northern tip experienced mean temperatures of 10 °C in summer, but these climatic optimums were likely intensely warm, short-lived interglacial phases within the overall trend of ice build-up during the late Pliocene/Quaternary transition.

Early to Late Quaternary

Terrestrial evidence for ice sheet size during the early to late Quaternary is limited and most scientific attention has focused on ice-sheet reconstructions during the Marine Isotope Stage (MIS) 11 (420–360 ka) and 5e (130–115 ka) interglacials, which are seen as potentially good analogs for the GrIS under future climate change. The Saalian stage (MIS 6 – 188–135 ka) was probably the largest glacial phase in the Quaternary from sedimentary evidence in east Greenland that the ice sheet

overran high mountain plateaux in this region during this time (Funder et al., 1998, 2011).

Direct evidence for the dimension of the GrIS during MIS 11, the so-called ‘super-interglacial’ (Augustin et al., 2004), is lacking. However, some data from far-field sites suggest that global sea level was up to 21 m above present during MIS 11 (Kaufman and Brigham-Grette, 1993; Olson and Hearty, 2009), and this would have required all of the Greenland, West Antarctic, and part of the East Antarctic ice sheets to melt. Sea-level reconstructions from this time interval are debated with, for example, the Red Sea sea-level record suggesting that the MIS 11 high stand was similar (within uncertainties (± 6.5 m)) to the Holocene (Rohling et al., 2010) (see [Eustatic Sea-Level Changes – Glacial-Interglacial Cycles](#)). This alternative interpretation would rule out catastrophic ice sheet collapse at both poles but the uncertainties in the latter reconstructions still allow for significant melt of the GrIS during this period.

The most compelling evidence of ice sheet retreat during the Quaternary is not from sea-level evidence but from a recent study of ancient DNA preserved in basal silty ice from the Dye 3 ice core in southern Greenland (Figure 1(a)). This study suggests that southern Greenland supported a similar boreal ecosystem to that at Kap København at some point

between 800–450 ka, with summer temperatures around 10 °C (Willerslev et al., 2007). In addition, a sea bed core offshore SW Greenland (ODP site 646) shows increased *Picea* pollen during MIS 11 (de Vernal and Hillaire-Marcel, 2008), adding weight to the hypothesis that southern Greenland was covered by boreal forest during this interglacial.

MIS 5e – The Eemian

Debates surrounding the size of the GrIS during the Eemian interglacial (130–115 ka BP) have been ongoing for over a decade. Paleoclimate data suggest peak summer temperatures ~4 and ~5 °C above present in northwest and east Greenland during this interglacial under higher than present solar insolation (Miller et al., 2006). A recent assessment of global sea-level records suggests that the GrIS contributed ~2.5 m to the global sea-level high stand of at least 6.6 m during this period, requiring significant melt of the ice sheet (Kopp et al., 2009).

Modeling experiments also suggest a smaller than present ice sheet during MIS 5e, although they are not all in agreement. For example, Cuffey and Marshall (2000) reconstruct a small, northern GrIS with almost all of southern Greenland ice free. They suggest an ice-equivalent global sea-level contribution of 4–5.5 m from Greenland. Tarasov and Peltier (2003) predict more conservative ice sheet retreat, with ice just covering the Dye-3 ice core location and a global sea-level contribution of between 2.7 and 4.5 m. Otto-Bliesner et al. (2006) infer a combined Greenland and Canadian Arctic contribution to global sea level of ~3.4 m, with a small southern ice cap separated from the larger northern Greenland ice sheet, and Robinson et al. (2011) agree that northern and southern domes are likely to have survived and estimate the global sea-level contribution at 3.7–4.4 m. Although these models differ in their initial set-up, their climate and their sea-level forcing, they all suggest that the GrIS contributed at least 2.7 m of global sea level during MIS 5e, and all suggest a significantly smaller (or absent) ice sheet in southern Greenland during the warmer than present conditions of this interglacial.

The presence of pre-Eemian plant remains at Dye3 (see above) has not solved the issue of ice sheet retreat from southern Greenland, because there is a significant hiatus between the age of silty basal ice (containing macrofossils and suggested to be ~450–800 ka old) and the overlying clean ice which is late MIS 5e in age (Alley et al., 2010). Alley et al. (2010) argue that the material contained in the basal ice may have been preserved as permafrost during MIS 5e when the GrIS had retreated north of this region. Results from a new deep ice core through the Eemian from northern Greenland (NEEM) should contribute toward our understanding of ice sheet melt and climate conditions during this interglacial period.

The same offshore sediment core that provides evidence for boreal forest during MIS 11 also provides evidence for a significantly smaller than present ice sheet during MIS 5e (de Vernal and Hillaire-Marcel, 2008). A rapid increase in alder pollen at the start of MIS 5e suggests high summer temperatures. A later peak in fern spores (*Osmunda*) is unparalleled in the last million years and indicates the development of dense fern vegetation over southern Greenland with conditions

comparable to that in modern boreal forests. Moreover, Carlson et al. (2008) use variations in Ti and Fe in a sediment core offshore of southwest Greenland as a proxy for terrestrial sediment carried by summer meltwater. They interpret high and constant Ti and Fe between ca. 132 and 120 ka BP as evidence that the GrIS was significantly smaller than present at this time and contributed a substantial proportion of the higher sea level during this interglacial.

RSL studies are relatively scarce during this period, but sediments preserved in and near Scoresby Sund, east Greenland, suggest that RSL fell from a marine limit of 70 m to below present sea level before rising to ~20 m (Funder et al., 1998). The magnitude of the RSL rise has no analog in the Holocene and Funder et al. suggest that it may be due to either glacio-isostatic depression during ice sheet readvance or large-scale eustatic melt from other far-field ice sheets after local melt had slowed or stopped. They favor the second hypothesis because macrofossils suggest the region was warmer than today during the transgressive phase, implying that this region of the GrIS had already deglaciated ahead of other far-field land-based ice masses (Funder et al., 2011).

The Last Deglaciation

The GrIS was at its maximum position during the LGM ca. 22–19 ka BP and in most locations ice extended offshore onto the continental shelf (Bennike and Björck, 2002; Funder and Hansen, 1996; Funder et al., 2011; Simpson et al., 2009). In some locations ice margin retreat across the shelf began by the start of the Late Glacial (~15–11.5 ka BP), and in all locations except for southern Greenland, ice retreat across the present coastline occurred only in the early Holocene (Bennike and Björck, 2002; Simpson et al., 2009). In southern Greenland, dates on the marine limit indicate ice sheet recession on land occurred at Qaqortoq and Nanortalik by ~11.0 and ~13.8 ka respectively (Bennike et al., 2002b; Sparrenbom et al., 2006a,b). In southeast Greenland, two studies report deglaciation in fjords near Ammassalik at ~9.9–9.7 ka BP (Long et al., 2008; Roberts et al., 2008).

After the ice sheet retreated onshore we can track when local ice-free conditions became established by inferring the timing of the local marine limit, by extending upward the local RSL curve to intersect the marine limit (Kelly, 1985; Weidick, 1972). However, this assumes that RSL fell immediately after deglaciation, which may not always have been the case (Funder and Hansen, 1996). Most RSL data from Greenland are from this period of rapid RSL fall, reflecting the availability of material for dating. A map of the marine limit for Greenland (Figure 1(b)) shows three domes of maximum uplift, one over the Sisimiut district in west Greenland (maximum ~140 m), one over the Scoresby Sund region in east Greenland (maximum ~135 m), and one on Hall Land in north Greenland (maximum ~130 m) (Weidick and Bennike, 2007). Low marine limits (~20 m) occur in regions where the ice sheet is currently close to the coast, such as in Melville Bugt in northwest Greenland and in parts of southeast Greenland. In these regions either ice volume has not changed significantly since the LGM or there has been significant build-up of ice during the late Holocene. Where there is a wide ice-free strip of land between the ice sheet and coast, the limit has a domed

appearance, rising from the outer coast to a maximum before decreasing toward the ice sheet margin (Funder and Hansen, 1996, Weidick, 1972).

Late-Glacial/Holocene RSL Changes in Greenland

Following the development of the radiocarbon dating technique, researchers in Holocene RSL in east and west Greenland began to develop local and regional chronologies for shoreline development and hence, ice sheet history. Pioneers of this approach dated marine molluscs and driftwood from Mesters Vig in east Greenland to develop two of the first radiocarbon-dated RSL records from Greenland, which revealed the classic pattern of rapid RSL fall during the early postglacial period, with RSL falling close to present by the mid-Holocene (Lasca, 1966; Washburn and Stuiver, 1962). Anker Weidick's work from the 1950s onward on systematic mapping and dating of marine and associated glacial deposits was the first to develop regional scale patterns of RSL change in west Greenland (Weidick, 1968).

Using similar methods, subsequent studies added new knowledge regarding the RSL and ice sheet history of other parts of Greenland (see reviews by Funder and Hansen, 1996; Kelly, 1985). Disko Bugt, a large marine embayment in central west Greenland, has become a particular focus for study because the ice sheet here is strongly influenced by the world's fastest flowing ice stream – Jakobshavn Isbrae, which drains a large portion of the GrIS and discharges ice into Disko Bugt and Baffin Bay. Since the late 1990s, researchers have developed several isolation basin records from Disko Bugt to understand the Holocene ice sheet history of this area, giving smaller age and altitude errors compared to earlier reconstruction methods (Long and Roberts, 2003; Long et al., 1999, 2003, 2006).

An isolation basin RSL record characteristic of postglacial uplift in west Greenland comes from Upernivik, midway along Jakobshavn Isfjord between the open coast of Disko Bugt and the ice sheet margin (Long et al., 2006) (Figure 2(a)). The marine limit, reflecting the timing of local deglaciation and amount of glacio-isostatic rebound in this area dates from ~8 k cal years BP and is ~41 m above present. The isolation basin staircase shows RSL fell steeply from this level in the early-mid Holocene, falling below present shortly before 4.5 k cal years BP. The lowstand in RSL is reached by ~3 k cal years BP at around –5 m before rising to present in the late Holocene. This pattern reflects initial glacio-isostatic rebound followed by depression during the mid-late Holocene neoglaciation period by glacial readvance and forebulge collapse (Kelly, 1980; Long et al., 2006).

This RSL record is similar to those found using isolation basins elsewhere in western Greenland during the Holocene. Figure 2(b) shows the Upernivik record together with two other isolation basin RSL histories from different regions of Greenland; Sisimiut (central west) and Nanortalik (south). The records from Upernivik and Sisimiut show RSL fell rapidly during the early and mid-Holocene, falling below present at or after ~4 k cal years BP and then rising by up to 5 m in the last 2–3 k cal years. The record from the far south of Greenland starts in the Late Glacial, where earlier ice-free conditions were established compared to areas to the north. Sparrenbom et al. (2006b) show that at Nanortalik RSL fell rapidly to below

present by ~10–8 k cal years BP, reached a lowstand (–6 m to –8 m) sometime in the mid-Holocene and then rose by an equivalent amount to present. The very quick fall in early and mid-Holocene RSL here shows that there was a rapid removal of a large volume of ice during ice margin retreat in this region (Sparrenbom et al., 2006a,b).

RSL Changes During the Neoglaciation and Last Millennium

Steeply falling RSL curves in the early Holocene, and a lack of RSL data from the mid- to late Holocene suggest that in many areas RSL fell below present in the mid-Holocene and has risen to present in the late Holocene. There are two hypotheses, not necessarily mutually exclusive, for the cause of this RSL rise. Rasch and Nielsen (1995) argue that J-shaped RSL curves reflect the collapse of the Greenland Ice Sheet forebulge. In contrast, Kelly (1980) and Weidick (1993, 1996) attribute late Holocene RSL rise to crustal reloading by neoglaciation ice sheet expansion from its mid-Holocene minimum during the Holocene climatic optimum (8–5 k cal years BP; Dahl-Jensen et al., 1998). Kelly (1980) calls the late Holocene RSL rise the 'Sandnes transgression' after a Norse church at Ameralik (west Greenland) that, it is claimed, has been lowered by between 5 and 6 m since AD 1600 by glacio-isostatic subsidence (Roussell, 1941). Evidence for ice sheet readvance during this period includes reworked organic material ripped up by the advancing ice sheet and deposited in recent moraines, and threshold lakes which are close to the ice sheet and record changes in the input of glacial material over time, recording local advance and retreat of the ice sheet margin (e.g., Briner et al., 2010; Kelly, 1980).

RSL data together with ice sheet models are particularly important in constraining the magnitude of ice sheet advance during the neoglaciation, because as an ice sheet re-advances it destroys terrestrial evidence of its former position. RSL data therefore provide an important context for interpreting recent ice sheet margin change (Long, 2009). Defining the Holocene sea-level lowstand is challenging but has been attempted using a variety of methods, including dating subaerially exposed desiccation surfaces in a marine core (Kelly, 1980), dating drowned beaches (Kuijpers et al., 1999), interpreting archaeological evidence (Kelly, 1980; Rasch and Jensen, 1997) as well as coring drowned isolation basins (Long et al., 1999, 2009; Sparrenbom et al., 2006a,b). Despite this range of indicators, we rely largely on submerged evidence from ingressed isolation basins now below high tide level. Ingression contacts in isolation basins are often eroded and measuring sill elevations is challenging when the sill is situated in or below the intertidal zone (Long et al., 2011).

The general pattern of late Holocene RSL change appears to be that the lowstand was reached earliest, and at greatest depth in the far south of Greenland. At Nanortalik, the lowstand was ~–8–~–6 m below present at ca. 7 k cal years BP, whereas at Upernivik in Disko Bugt, it occurred at ~–3–~–4 m between 3 and 2 k cal years BP (Figure 2(b)). The difference in timing and magnitude of the lowstand between these two locations in south and west Greenland reflects differences in the timing of deglaciation during the Holocene, the thickness of the local (Greenland) and non-local (especially North American) ice at the LGM causing glacio-isostatic rebound,

Figure 2 (a) Isolation basin RSL data from Upernivik, Disko Bugt, west Greenland (Long et al., 2006) and photos showing two of the lower basins. The two index points below present sea-level record first basin isolation and then regression during the late Holocene. (b) Isolation basin RSL data from three sites in west and southern Greenland; Upernivik, Disko Bugt (Long et al., 2006), Sisimiut, central west Greenland (Long et al., 2009; Bennike et al., 2011) and Nanortalik, south Greenland (Sparrenbom et al., 2006b). Note the lowest isolation basin of Bennike et al., (2011), at ~18 m, is very shallow and contains an incomplete sedimentary record so is not included here.

and the increase in ice mass and therefore reloading during the neoglacial period between southern and western Greenland. However, the complex interactions of these different factors means that differences in the magnitude and timing of RSL changes across west Greenland should be interpreted cautiously in terms of neoglacial changes in ice load (Long et al., 2009).

An additional approach which has been used to obtain RSL data from the last millennium is to study salt marsh deposits in protected coastal locations in the southern half of Greenland. Marshes exist on the open coast from at least Disko Bugt

southward and record RSL rise over the past millennium in their stratigraphy (e.g., Woodroffe and Long 2009). Although the marshes have low sedimentation rates their sediments have survived under persistent RSL rise and contain precise evidence for RSL changes during the last few centuries. RSL reconstructions using a diatom-based transfer function approach on individual sediment profiles and multiple basal samples show that the RSL rise reconstructed from isolation basins continues until approximately AD 1600 in central west Greenland (Sisimiut), and between AD 1750 and 1950 in southern Greenland (Nanortalik) (Long et al., 2012)

Figure 3 (a) Photograph of a typical thin salt marsh sediment sequence found in west Greenland, showing an upward transition from freshwater to salt marsh sediments formed by RSL rise over the past few hundred years. Also shown is a photograph of a modern salt marsh near Paamiut, in southwest Greenland. (b) RSL reconstructions from salt marshes at Aasiaat, Sisimiut, and Nanortalik together with isolation basin data from each area for the past 2700 years (modified from Long AJ, Woodroffe SA, Milne GA, Bryant CL, Simpson MJR, and Wake LM (2012) Relative sea-level change in Greenland during the last 700 years and ice sheet response to the Little Ice Age. *Earth and Planetary Science Letters* 315: 76–85, including isolation basin data from Long et al. 2003 (Outer Disko Bugt), Long et al., 2009 (Sisimiut) and Sparrenbom et al., 2006b (Nanortalik)).

(Figure 3). Since that time RSL has been stable, which is consistent with local ice mass loss in west Greenland (Wake et al., 2012).

Conclusions

Greenland is an important laboratory for the investigation of RSL change as it is the only location in the Northern Hemisphere where a continental-scale ice sheet which was present at the LGM remains today. Sedimentary evidence from before the LGM is rather limited, mainly because the expansion of the ice sheet onto the continental shelf in many areas during the LGM destroyed evidence of older deposits. However, borehole evidence from the ice sheet itself, notably from the Dye-3 drilling site in south Greenland, together with sediment cores from the offshore of southwest Greenland, strongly indicate a significantly smaller than present ice sheet during MIS 5e, contributing at least 2.4 m to global sea level (Kopp et al., 2009). During the Late Glacial and Holocene, more abundant deposits show that rapid glacio-isostatic rebound dominated in the early and mid-Holocene, followed by RSL fall below present and subsequent rise in the late Holocene. These typical J-shaped RSL curves are observed in many regions. Differences in the detail of the curves point to variations in regional to local-scale ice sheet history.

Long-term trends in Holocene RSL are useful in establishing millennial-scale patterns of ice sheet history and much emphasis to date has been on the early and mid-Holocene, since data from this period is the most abundant. A major scientific challenge is to extend these Holocene records up to the present-day, ideally so they can provide a longer term context for geodetic observations, notably GPS and gravity observations (e.g., Khan et al., 2010; Rignot et al., 2011), that provide so much concern regarding the ice sheet's response to recent climate change. In this area, Quaternary scientists have an important role to play in seeking to identify whether the patterns observed over short-time intervals, measured in years or a few decades, represent significant long-term trends or simply part of the variability that is inherent in a dynamic ice sheet.

Introduction

The dominant influence on relative sea-level (RSL) changes since the Last Glacial Maximum (LGM; 26 ka BP) has been the melting of approximately 50 million km³ of land-based ice as Earth's climate transitioned from glacial to interglacial conditions. Transfer of this mass to global ocean basins increased ocean water volume and caused a large and ongoing isostatic response of the solid Earth ([Figure 1](#)). The largest RSL changes occurred in regions such as Canada and Fennoscandia, which were beneath continental-scale ice sheets at the LGM. These *near-field* regions are characterized by continuous RSL fall, because the rate of glacio-isostatic uplift exceeded the rate of eustatic sea-level rise. Depression of land beneath LGM ice sheets was compensated for by migration of mantle material away from ice-load centers that caused uplift of a forebulge in regions peripheral to ice sheets. These *intermediate-field* regions (e.g., mid-Atlantic coast of the United States) also have deglacial RSL histories influenced by glacio-isostasy. As land-based ice diminished, mantle material returned to the former load centers causing collapse and retreat (glacio-isostatic subsidence) of the forebulge. Thus, isostatic and eustatic effects worked together to cause RSL rise. Reduction in meltwater input after 7 ka BP slowed RSL rise and increased the relative contribution from glacio-isostatic subsidence. Ongoing subsidence in these regions caused late Holocene RSL rise in the absence of a eustatic contribution. At increasing distances from major ice centers, eustatic contributions to RSL change exceeded glacio-isostatic contributions. Regions not significantly influenced by glacio-isostasy are termed *far field*. At tectonically stable far-field locations, RSL changes are an approximation of the eustatic component. However, a number of processes including hydro-isostatic subsidence of ocean basins and perturbations to Earth's rotation driven by mass redistribution cause RSL changes in far-field regions to depart from the eustatic value.

[Clarke et al. \(1978\)](#) seminal paper identified five principal forms of the sea-level curve (plus a transitional form), reflecting variable RSL histories on near-, intermediate-, and far-field coastlines ([Figure 2](#)). These predicted curves provide a general description of deglacial RSL changes but do not reflect the uncertainty associated with geological reconstructions of RSL. The original work of [Clark et al. \(1978\)](#) has been extended to incorporate recent developments in the understanding of the history of eustatic contributions, lateral shifts in shoreline position associated with local sea-level changes, growth and retreat of marine-based ice sheets, feedback from glaciation-induced perturbations in Earth rotation, and gravitational changes in sea level caused by redistribution of mass ([Milne and Mitrovica, 2008](#)).

Late Quaternary Sea Levels

We summarize RSL data from passive coastal margins at mid-latitudes to show patterns of RSL changes since the LGM. We also draw attention to recent advances in the understanding of RSL changes during the past 2 ka. In some instances, processes that may have caused the RSL changes are described. Selected studies from the Atlantic coast of North and South America, Europe, China, South Africa, and Australasia are highlighted as representative examples of regional RSL histories that correspond to [Clark et al. \(1978\)](#) zones I, II, and V. The examples were drawn purposefully from studies published in the last 20 years and are intended as an introduction to Holocene sea-level histories. References to older studies (and ones from other regions) can be found in this modern body of literature. In the examples used, RSL data comprise sea-level index points that estimate the unique position of RSL in space and time ([Engelhart et al., 2009](#)) and are used to describe the form of RSL changes and estimate rates of change. The interpretation of index points was not changed from that in the original studies. Negative values indicate a RSL below the present level. Where necessary, we have converted radiocarbon ages into 1000 calibrated years (ka) before present (BP) where year 0 is conventionally taken to be AD 1950. For clarity, we describe most ages to the nearest 0.1 ka without chronological uncertainty.

Atlantic Coast of North America

The *Atlantic coast of Canada* and *Gulf of Maine* include near- and intermediate-field regions. [Shaw et al. \(2002\)](#) compiled sea-level index points from Atlantic Canada since the LGM. Newfoundland experienced continuous RSL fall because of isostatic uplift caused by ice unloading. RSL reconstructions from Labrador also showed falling RSL throughout the post-glacial period from a maximum marine limit of +120 m at 16 ka BP. The exception is the northern Labrador Peninsula where RSL fell below 0 m at 7.7 ka BP. In Nova Scotia, there was a RSL lowstand of –65 m at 13.5 ka BP, since when RSL has risen at a decreasing rate through the Holocene ([Shaw et al., 2002](#)). A study of sea-level changes during the past 1 ka using Foraminifera preserved in salt-marsh sediment showed that RSL in Nova Scotia rose at 1.6–1.7 mm year^{–1} until the start of the twentieth century when the rate increased to 3.2 mm year^{–1} ([Gehrels et al., 2005](#)).

Isostatic rebound dominated the RSL history of the Gulf of Maine ([Figure 3\(a\)](#)). Retreat of the Laurentide Ice Sheet exposed large areas of isostatically subsided land that were rapidly submerged ([Kelley et al., 2010](#)). Maximum RSL occurred at 17 ka BP and was 70–129 m above the present level.

Figure 1 Schematic representation of glacial isostatic adjustment: the response of the solid earth to loading by an ice sheet as observed at near-, intermediate-, and far-field sites. (a) Commencing from isostatic equilibrium, the addition of an ice sheet causes the land below it to subside and pushes a peripheral bulge away from the load. On deglaciation, the mantle material flows back toward the former ice-sheet

Glacio-isostatic uplift caused RSL to fall to a lowstand of -60 to -65 m at 12 ka BP. This lowstand was brief and RSL rose rapidly to -20 m at 11.5 ka BP. RSL remained at this level for 3.5 ka: a period termed the sea-level 'slowstand' (Kelley et al., 2010). Subsequently, the rate of glacio-isostatic rebound slowed and was surpassed by eustatic contributions causing RSL rise. Sea-level rise over the past 4 ka was less than 1 mm year^{-1} (Engelhart et al., 2009). High-resolution reconstructions show that this late Holocene rate of RSL rise, driven solely by isostatic factors, was exceeded in the nineteenth century, since when RSL has risen by 0.3–0.4 m (Gehrels et al., 2002).

The Atlantic coast of the United States from New Hampshire to South Carolina is an intermediate-field region. Glacio-isostatic contributions were much reduced in magnitude compared to those of Atlantic Canada or Maine but remain the dominant influence. The coastline in this region is subsiding in response to collapse and retreat of the Laurentide Ice Sheet forebulge and return flow of mantle material toward formerly glaciated areas. RSL records are characterized by continual rise during the Holocene, with the rate slowing through time because of continued, but decreasing, glacio-isostatic subsidence. In Massachusetts, RSL was -120 m at the LGM and -65 m at 13.5 ka BP. It subsequently rose at approximately 6 mm year^{-1} to -7 m at 4.5 ka BP (Uchupi et al., 2005). In the late Holocene, the rate of RSL rise was reduced to 2 mm year^{-1} . Using salt-marsh sediments, Donnelly (2006) showed RSL to have been -2.6 m at 3.3 ka BP, after which it rose by 0.8 mm year^{-1} until 1 ka BP and since then by 0.5 mm year^{-1} . In Connecticut, a late Holocene rise of 1 mm year^{-1} , which was driven by isostatic subsidence, was punctuated by a sea-level oscillation at 1 ka BP (Medieval Climate Anomaly) when sea level was 25 ± 25 cm higher than AD 1650 (Little Ice Age; van de Plassche, 2000). Donnelly et al. (2004) identified the onset of recent, higher rates of rise (3 mm year^{-1}) at around AD 1850.

Several studies have reconstructed Holocene RSL in New Jersey and Delaware. Miller et al. (2009) showed that RSL in New Jersey rose from -18 m at 8.5 ka BP to -9 m at 5 ka BP. Thereafter, RSL rose at 1.8 mm year^{-1} until 0.5 ka BP. In Delaware, RSL was -27 m at 12 ka BP (Nikitina et al., 2000). RSL rose at more than 3 mm year^{-1} between 7 and 5 ka BP, before slowing down to 2.1 mm year^{-1} from 5 to 2 ka BP and 0.9 mm year^{-1} from 1.3 ka BP to AD 1900. RSL rise increased to 3.3 mm year^{-1} in the twentieth century (Nikitina et al., 2000). Engelhart et al. (2009) compilation of sea-level index points showed that New Jersey and Delaware experienced the highest rates of RSL rise on the Atlantic coast of the United States during the past 4 ka (up to 1.7 mm year^{-1}), because they are located near the center of proglacial forebulge collapse.

Horton et al. (2009) showed that RSL in North Carolina rose from -36 m at 11 ka BP to -4 m at 4 ka BP, which equated to an average rate of rise during the early and mid-Holocene of 5 mm year^{-1} (Figure 3(b)). RSL rise slowed in the late Holocene to 1 mm year^{-1} (Engelhart et al., 2009). A study of RSL changes during the past 0.5 ka showed that the late

load until equilibrium is reached once more. (b) The isostatically induced land movement at near-, intermediate-, and far-field sites associated with the glacial and deglacial cycle in (a).

Figure 2 Relative sea-level (RSL) curves predicted by Clark et al. (1978). Under an assumption of eustatic input ending at 4 ka BP, five sea-level zones (I–V) plus a transitional zone (I–II) were recognized. All x-axes are 1000 calibrated years before present (ka BP).

Holocene, isostatically driven, rate of rise has been exceeded since the end of the nineteenth century (Kemp et al., 2009). Further south along the Atlantic coast of the United States, the contribution from glacio-isostatic subsidence is reduced in magnitude. This can be seen in the RSL history of southern *South Carolina*, where the rate of late Holocene sea-level rise was 0.6 mm year^{-1} (Engelhart et al., 2009).

Europe

RSL reconstructions from mid-latitudes in Europe define areas of postglacial isostatic rebound (e.g., Sweden and Scotland) and subsidence (e.g., the Netherlands and Germany). The Baltic Ice Lake (a proto-Baltic Sea) formed around 14 ka BP following ice margin readvance in northern *Estonia* (Raukas, 2000). Retreat of continental ice lowered the Baltic Ice Lake level by 25–30 m at 12.5 ka BP. RSL rose to 42–45 m above the present level at 10 ka BP and subsequently fell by 30–35 m between 9 and 8 ka BP (Raukas, 2000). Eustatic contributions exceeded the rate of glacio-isostatic land uplift from 8.4 to 6.8 ka BP, causing RSL rise (Raukas, 2000). Isolation basins in southeastern Sweden (Berglund et al., 2005) recorded RSL fall at 8.1 ka BP, which was correlated with the 8.2 ka BP climate event. This event was an abrupt, widespread climate instability that Berglund et al. (2005) suggested was associated with a positive phase of North Atlantic Oscillation leading to high atmospheric pressure over the Baltic Sea with strong northern winds and lowered mean sea level. Yu et al. (2007) identified an abrupt (occurring over less than 200 years) RSL rise of 4.5 m at 7.6 ka BP in southeastern Sweden likely caused by the final decay of the Labrador sector of the Laurentide Ice Sheet (Figure 3(c)). Since the mid-Holocene, there was

continuous RSL fall in the southern Baltic due to slow isostatic adjustment (uplift) and limited eustatic input.

Owing to its location at the margin of the former Fennoscandian Ice Sheet, northern *Denmark* experienced RSL fall since the LGM, while areas to the south experienced RSL rise. Clemmensen et al. (2001) reconstructed Holocene RSL for Skagen at the northern tip of Denmark. RSL fell from +12 to +1 m between 5.6 and 1.4 ka BP. In Ho Bugt (western Denmark), Gehrels et al. (2006) used basal salt-marsh peats to show that 4 m of RSL rise has occurred since 4 ka BP. Numerical modeling of glacial isostatic adjustment in this region suggests that this rise can be adequately explained by land subsidence alone. Szkornik et al. (2008) suggested that this rise was punctuated by two periods with greater than average rates of sea-level rise. The first was between 2 and 1.4 ka BP and the second commenced at AD 1500. *Baltic Germany* lies beyond the margins of the former Fennoscandian Ice Sheet. RSL rose rapidly there (20 mm year^{-1}) from 8 to 5.7 ka BP, after which it rose gradually to present (Meyer and Harff, 2005).

Shennan and Horton (2002) provided a synthesis of RSL data and proposed summary RSL curves for 52 areas in the *United Kingdom*. This dataset was recently reviewed by Gehrels (2010). Although small in global terms, the British Ice Sheet was large enough for glacial isostatic adjustment to produce spatially variable RSL histories. At Arisaig (northwest Scotland), which was covered by relatively thick ice (900 m) at the LGM, RSL fell from a marine limit between +36 and +40 m at 16 ka BP to an early Holocene minimum (11 ka BP) of +3 m (Figure 3(d)). RSL reached a mid-Holocene highstand (+6.5 m) that persisted from 8 to 5 ka BP. In the United Kingdom, there were clear north–south variations in RSL. For example, along the east coast of England, at

Figure 3 Selected relative sea-level reconstructions from mid-latitudes: (a) Maine, USA (Kelley et al., 2010); (b) North Carolina, USA (Horton et al., 2009); (c) Baltic coast of Sweden (Yu et al., 2007); (d) Arisaig, Scotland (Shennan and Horton, 2002); (e) The Netherlands (Hijma and Cohen, 2010); (f) Yangtze Delta, China (Zong, 2004); (g) New South Wales (NSW), Australia (Sloss et al., 2005); (h) southwest South Africa (Compton, 2001); (i) Patagonia, Argentina (Rostami et al., 2000). The spatial areas of Clarke et al. (1978) five types of 'sea-level curve' (I–V) are shown. Altitudes and interpretation of sea-level index points (including errors) have not been amended from the original publication. All y-axes are relative sea level (meters to present). Radiocarbon ages were converted to calibrated dates where necessary, all x-axes are in 1000 calibrated years before present (ka BP). Index points are represented as + symbols, and in some instances, errors may be plotted larger than the original publication to aid in clear visual presentation (e.g., Maine).

8 ka BP, RSL in Northumberland was 20 m higher than that in Norfolk. Sea-level index points from Northumberland showed rising RSL from -5 m at 8.6 ka BP to a mid-Holocene maximum of $+2.5$ m at 3–4 ka BP. In Norfolk, RSL rose from -13.5 m at 7.5 ka BP to -4.0 m at 5.3 ka BP, which equates to a mean rate of 4 mm year^{-1} . The maximum late Holocene glacio-isostatic uplift (1.7 mm year^{-1}) occurred in central and western Scotland, while the maximum subsidence (1 mm year^{-1}) occurred in the southwest of England (Gehrels, 2010).

Using a similar database approach, Brooks et al. (2008) collated sea-level index points for Ireland. The data displayed a coherent and consistent pattern of RSL change in southern Ireland driven by forebulge collapse. For example, RSL in East Cork rose from -18 m at 9 ka BP to -5 m at 7 ka, followed by a slow rise in RSL of 0.7 mm year^{-1} to present. In northeast

Ireland, RSL history was more complicated because of variable isostatic influence.

In the southern North Sea, RSL has risen continuously since the LGM. RSL was 110–130 m below the present level at the LGM, which exposed much of the North Sea basin as dry land (Streif, 2004). RSL rose from -72 m at 12.5 ka BP to -25 m at 7.5 ka BP; the average rate of RSL rise was 15 mm year^{-1} but was 21 mm year^{-1} between 9.9 and 7.7 ka BP, after which RSL rose at a decreasing rate to present (Streif, 2004).

On the Belgian coastal plain, Denys and Baeteman (1995) reconstructed Holocene RSL rise during deglaciation using basal salt-marsh peats and showed rates of 7 mm year^{-1} from 9.4 to 7.5 ka BP. This caused rapid transgression of the continental shelf toward a position close to the present-day boundary of the coastal plain. After 7.5 ka BP, the rate of rise

decreased to 2.5 mm year^{-1} with a further fall to 0.7 mm year^{-1} since 5.5–5 ka BP (Denys and Baeteman, 1995). Hijma and Cohen (2010) suggested that in the Netherlands, RSL rose at $9\text{--}10 \text{ mm year}^{-1}$ from 9 to 7.5 ka BP, with a jump in RSL of 4 m commencing at 8.45 ka BP and lasting less than 200 years (Figure 3(e)). Catastrophic outflow of proglacial lakes Agassiz and Ojibway through the Hudson Strait was proposed as the cause of this jump (Hijma and Cohen, 2010).

Sea-level reconstructions from Atlantic France showed RSL rise prior to 7.5 ka BP, with no evidence of RSL being above the present level (Allard et al., 2008). In Portugal, RSL was -100 m at 16 ka BP and rose to -40 m between 12 and 11 ka BP (Dias et al., 2000). Boski et al. (2008) indicated that during the Holocene, RSL rose by 8.5 mm year^{-1} to approximately 6.5 ka BP and 3 mm year^{-1} until 5 ka BP, when RSL approached the present level. In Spain, RSL rose at $0.25 \text{ mm year}^{-1}$ after 0.5 ka BP because of isostatic adjustment until a change to modern rates of rise at the start of the twentieth century (Leorri et al., 2008).

China

Reconstructions from China indicate a complicated history of Holocene RSL changes, including debate about the existence of a mid-Holocene highstand (Zong, 2004). Sea-level index points from mid-latitude locations in China (southern edge of the Yangtze Delta plain and the Taihu area) were compiled by Zong (2004). RSL in the Yangtze Delta region rose from -20 m at 9.5 ka BP to -5 m at 8 ka BP, since when the rate of RSL rise has been less (1 mm year^{-1}). Since 3 ka BP, RSL has been close to 0 m (Figure 3(f)).

Australasia

Australia has been an important far-field location for RSL reconstruction, including the first widely proposed eustatic sea-level curve and early debates on hydro-isostasy. RSL reconstructions from mid-latitudes including New South Wales (Figure 3(g)) showed that RSL rose from -120 m at the LGM to $+1 \text{ m}$ at 7.2 ka BP (Sloss et al., 2005). In South Australia and Tasmania, RSL had risen sufficiently by 20 ka BP to enter the Bass Basin and form an estuarine environment that isolated Tasmania from the Australian mainland at 17 ka BP (Lambeck and Chappell, 2001). In Western Australia, RSL was between -50 and -40 m at 11.5–13 ka BP (Lessa and Masselink, 2006).

A prominent feature of Australian Holocene RSL records is the mid-Holocene highstand. Lewis et al. (2008) compilation of RSL data from eastern Australia using coral microatolls and fixed biological indicators (oyster beds and tubeworms) suggested that RSL reached a maximum of $+1.0$ to $+1.5 \text{ m}$ at 7 ka BP. In southeastern Australia, the maximum RSL was $+1.5 \text{ m}$ at 7.5 ka BP (Sloss et al., 2005). Sites on the south coast of Western Australia recorded a maximum RSL of $+1 \text{ m}$ at 7.5 ka BP (Lessa and Masselink, 2006).

RSL fall from the highstand was caused by ocean siphoning (Milne et al., 2005). Along the eastern Australian coast, Lewis et al. (2008) suggested, the fall included two $0.3\text{--}1.0 \text{ m}$ oscillations at 4.6 and 2.9 ka BP. In contrast, Sloss et al. (2005) suggested that RSL remained within 0.5 m of the highstand for 6.5 ka before a gradual fall to 0 m at 2 ka BP (Figure 3(g)).

Similarly, Lessa and Masselink (2006) suggest that RSL maintained its highstand elevation for much of the middle and late Holocene before falling to the present level since 2.5 ka BP.

The most complete Holocene RSL record for New Zealand is based on data from tectonically 'quiet' areas near Dunedin and Auckland (Hayward et al., 2002). Sea level rose from -25 m at 9 ka BP to reach 0 m at 7 ka BP. Since then, RSL has been no more than 1 m above and no less than 0.5 m below the present level. A reconstruction of RSL since 0.5 ka BP using Foraminifera preserved in salt-marsh sediments showed that RSL in New Zealand rose slowly ($0.3 \pm 0.3 \text{ mm year}^{-1}$) until the twentieth century when the rate increased to 2.8 mm year^{-1} (Gehrels et al., 2008).

South Africa

Being remote from Quaternary ice sheets, the South African coast experienced only minor isostatic movements. A Holocene RSL record developed from beachrock showed that RSL rose at 8 mm year^{-1} between 10.5 and 8.5 ka BP, reaching 0 m at 7.4 ka BP (Ramsay, 1996). It then rose to a mid-Holocene highstand of $+3.5 \text{ m}$ at 5.5 ka BP. Ramsay (1996) suggested that RSL fell to -2 m at 3.2 ka BP and subsequently rose to $+1.5 \text{ m}$ at 1.5 ka BP before falling to 0 m at 0.9 ka BP. This oscillation in the late Holocene RSL record may have been due to ocean siphoning and warmer ocean temperatures of the eastern Agulhas Bank (Ramsay, 1996). Compton's (2001) investigation of salt-marsh lagoons on the southwest coast of South Africa supported the presence of a mid-Holocene highstand with similar 1-m-scale RSL fluctuations in the late Holocene (Figure 3(h)).

South America

There have been two recent analyses of RSL data from the Atlantic coast of South America. Peltier (2002) demonstrated that this region was strongly influenced by rotational feedback, causing an elevated mid-Holocene highstand. Using mollusk shells from raised beaches that were dated using uranium-series, electric spin resonance, and radiocarbon methods, Rostami et al. (2000) produced a RSL record for Patagonia that showed a highstand of $+6 \text{ m}$ at 8 ka BP, with a gradual fall to present (Figure 3(i)). Milne et al. (2005) divided a RSL dataset of radiocarbon-dated organic sediments and shells into regions to identify spatial trends in Patagonia. Data from the Strait of Magellan showed RSL to be $+1 \text{ m}$ at 9 ka BP, with limited change ($\pm 1 \text{ m}$) to 5 ka BP. RSL data from the Beagle Channel demonstrated a highstand of $+6 \text{ m}$ at 6 ka BP, followed by a fall to 0 m by 3 ka BP.

Conclusion

RSL data from mid-latitudes reveal spatial and temporal changes caused by the varying dominance of eustatic and isostatic (glacio and hydro) factors since the LGM. Near-field regions (e.g., Atlantic coast of Canada, Sweden, and Scotland) are characterized by a complex sea-level fall from a maximum marine limit, reflecting the interplay between eustatic sea-level rise and glacial-isostatic uplift. In intermediate-field regions

such as mid-Atlantic coast of the United States, isostatic and eustatic effects combined to cause RSL rise. Recent research in northwestern Europe (e.g., the Netherlands) has identified rapid RSL rises and falls during the Holocene. A feature of sea-level records from mid-latitude, far-field locations is the mid-Holocene highstand, which differs in timing and magnitude across sites from Australasia, South Africa, and South America. Detailed RSL reconstructions from salt marshes have led to an improved understanding of sea level during the last 2000 years. A common feature of these records is an increase to modern rates of RSL rise that was likely initiated at the end of the nineteenth or early twentieth century.

Late Quaternary Relative Sea-Level Changes in the Tropics

Y Zong, The University of Hong Kong, Hong Kong

© 2013 Elsevier B.V. All rights reserved.

Introduction

The tropical zone is commonly defined by the parallels of Tropic of Cancer at 23°30'N and Tropic of Capricorn at 23°30'S. In recent decades, the tropics have been researched intensively for the history of Late Quaternary relative sea-level (RSL) changes. These studies are important because data from the tropics can be used to reconstruct the history of eustatic sea-level changes as the tropics have not been affected by the glacio-isostatic processes that influenced areas close to former ice sheets in the polar regions.

For some time now, geophysical models have been capable of predicting local and regional RSL for any coastal site on Earth. Because of the varied interplay between eustatic and glacio- and hydro-isostatic processes, RSL records are highly varied; therefore, it is useful to distinguish between records from 'far-', 'intermediate-', and 'near'-field sites (Long, 2001). Far-field sites are where the hydro-isostatic signal outweighs the glacio-isostatic signal because they are areas far from the former ice sheet margins. Far-field sites are defined as the area between about 30°N and 30°S, within which the tropics lie.

Because of the distinctive RSL history in far-field sites, the patterns of coastal evolution are important issues for the tropics. For instance, the directions and paces of shoreline movement in large estuaries and deltas during the Holocene have been controlled to a certain extent by changes of RSL. Looking into the future, many low-lying coastal areas in the tropics, such as the Maldives in the Indian Ocean and many similar atolls in the Pacific Ocean, and the ecosystems therein, will become vulnerable to, or affected by, RSL rise in the near future as a result of global climatic warming.

Sea-Level Indicators

There are a number of sea-level indicators found uniquely in the tropics. These indicators include coral, mangrove, beach rock, and tubeworm. They live or form close to sea level. Their carbonate structures or organic materials enable us to determine the age of each sample by the use of radiometric dating methods. With the age, altitude and indicative meaning, they can be used as sea-level index points for the reconstruction of the Late Quaternary history of RSL changes. The spatial distribution of these indicators is generally confined by nature. For instance, the southern and northern limits of coral and mangrove distributions closely follow the 20 °C isotherm of winter average sea surface temperature (SST; Figure 1). Each type of sea-level indicators has its own strength and limitations. Details of these sea-level indicators are discussed below with special attention given to issues associated with dating and indicative meaning.

Coral

Although corals are common throughout the world's oceans, the reef-building, or hermatypic, corals are restricted to tropical or subtropical latitudes, roughly between the 30°N and 30°S parallels where SST does not fall below 20 °C in the coldest month of the year, and to relatively shallow (<100 m) waters. The basic unit of the reef-building corals is the polyp, which sits within an external skeleton of calcium carbonate secreted by the outer layer of the coral tissue.

Over time as the coral grows, new skeletal material is laid down so that while the structure of the coral may be considerable, only the outermost layer is living tissue. Polyp colonies are normally long-lived, spanning hundreds to thousands of years. Together with a number of interlocking elements, including autochthonous and allochthonous remains of animals and plants, clastic sediment and chemical alteration processes, they produce massive calcareous structures close to sea level (Figure 2). Growth rates of about 10–30 mm years⁻¹ are common (Lowe and Walker, 1997). Gradual rise in sea level has enabled reefs to build vertically, maintaining their shallow-water habitat over time, and thus provide crucial records of sea-level movements.

There are, however, a number of issues that are associated with the application of corals to sea-level studies. The most important one is to establish the indicative meaning of the coral specimen under study, because different coral species live under different water depths. A reef-crest coral *Acropora palmata*, for example, is the best suited to sea-level studies as this species is generally restricted to the upper 5 m of water and dominates the reef-crest community in many locations of the Caribbean. Coral samples can be dated by radiocarbon dating methods and the U–Th method which is significantly more precise than the former (Walker, 2005; Yu and Zhao, 2009).

Mangrove

Mangrove swamps or forests occur in almost the same climate zone as coral, that is, between the 30°N and 30°S parallels (Figure 1). While corals enjoy living in clear water, mangroves prefer coastal sites where there are muddy or fine-grained sediments (Figure 3). Within coastal settings, mangroves' distribution and species composition vary considerably. Although extending into the marine environment, mangrove forest is nevertheless a terrestrial ecosystem, linked to the hinterland landform, vegetation and hydrology. Therefore, zonations of mangroves are peculiarly site specific (Clough, 1982).

The strength of mangrove deposits being used for sea-level studies lies in the fact that the rich organic carbon contained in mangrove deposits can be dated by radiocarbon methods, and the fact that mangrove communities live close to local mean high water levels (Figure 4(a)). Therefore, the indicative meaning for mangrove samples can be determined within a

Figure 1 The distribution of reef-building corals and mangroves are generally limited to the 20 °C isotherm of winter average sea surface temperature, which roughly follow the 30° N and 30° S parallels. Most beach rocks are also found within this zone, although tubeworms extend further into mid-latitudes.

Figure 2 A coral reef (*Acropora palmata*) of mid-Holocene in age emerged above local mean sea level in Barbados. ©2005, Photograph by A.J. Long.

narrow altitudinal error band. Furthermore, microfossil pollen, diatom, and Foraminifera are generally well preserved within mangrove deposits (Horton et al., 2005; Zong and Kamaludin, 2004), and microfossil analysis can help determine the indicative meaning for a dated horizon (Horton et al., 2007). As a result, mangrove deposits (Figure 4(b)) have been widely used as sea-level indicators.

On a regional scale, mangrove development and decline can be linked to specific phases of Late Quaternary sea-level change. Data from the north Australian continental shelf indicate that mangrove expansion occurs during marine transgressions, whereas mangrove contraction occurs during marine regressions. The dominant factor controlling the cycle of expansion and decline of mangrove communities is explained in

Figure 3 Mangrove forest (*Rhizophora* sp.) colonized on a tidal mudflat in Hong Kong. ©2010, Photograph by Y. Zong.

terms of contrasting physiographic conditions of coasts during transgressive and regressive phases, in particular by the existence, or lack, of well-developed tidal estuaries (Grindrod et al., 1999).

Beach Rock, Oysters, and Tubeworms

Beach rock, in the form of cemented sandstone, is widely recorded from sandy beaches in the tropics and subtropics as a mixture of sand grains and calcareous marine biofragments that have undergone marine processes of cementation. Beach rock has developed in the kind of climatic and physiographical conditions in which calcium carbonate cements have been precipitated from sea water and come from beach sediments.

Figure 4 A transect of mangrove forest (a) recorded on the east coast of Peninsular Malaysia shows the pioneer mangrove vegetation is confined within local mean high water of neap tides and mean high water of spring tides. Mature mangrove vegetation grow between local mean high water of spring tides and tidal limit, above which terrestrial vegetation occupies. Sequences of tidal flat and mangrove deposit can be obtained from many coastal sites, and the contact between tidal flat sediment and mangrove peat (b) can be used as sea-level indicator. EHW, Extremely high water; HAT, highest astronomical tide; MHHW, mean higher high water; MHWN, mean high water neaps; MHWS, mean high water springs; MLHW, mean lower high water. Reproduced from Zong Y and Kamaludin BH (2004) Diatom assemblages from two mangrove tidal flats in Peninsular Malaysia. *Diatom Research* 19: 329–344.

Beach-rock forms in the upper part of a beach, generally between mean sea level and mean high water levels (Figure 5). In other words, the indicative meaning and altitudinal error for beach rock can be readily estimated. The main concern for using beach-rock data for sea-level studies lies in the considerable uncertainties associated with the age of a beach-rock sample: the cement materials, mostly calcite and aragonite, may have formed significantly later than the calcareous marine biofragments.

Shells of oyster and tubeworm are also useful proxies of RSL as they are found in coasts across the tropics. Oysters (such as *Saccostrea cucullata*) and tubeworms (such as *Galeolaria caespitosa*) fix their shells on rock faces and normally occur in a tightly constrained altitudinal zone. Therefore, the indicative meaning can be easily determined and their error ranges are as narrow as 0.1 m in the case of certain species (Baker et al., 2001).

Late Quaternary RSL Records

Eustatic Sea-Level History and Climate Change

The tropics as a far-field site has yielded RSL records that provide a reasonable approximation of eustatic changes linked to glacial cycles, because the combined glacio- and hydro-isostatic effects in far-field sites are usually small. RSL data from the tropics have been used to constrain geophysical models concerning eustatic sea level since the Last Glacial Maximum (LGM) and eustatic contribution of major ice sheets. Observations of RSL in the tropics are therefore crucial to improving the predictive power of geophysical models. In particular, it is important to identify the key reference point for the beginning of deglaciation, periods of rapid sea-level rise, and the early-middle Holocene slowdown of RSL, as well as to identify sites where the RSL curves switch from rising to falling during the mid-Holocene.

Late Quaternary sea-level history comprises the time span of a full glacial cycle, that is, from the last interglacial, through the last glacial, to the present interglacial. Evidence of RSL changes in the tropics can be discerned for four distinctive periods: sea-level highstand of the last interglacial, sea-level lowstand during the LGM, rapid sea-level rise from the Late Glacial to early Holocene and sea-level highstand during middle to late Holocene. To understand the distinctive characteristics of these intervals, the following sections review age/altitude evidence of RSL for each of the four periods.

Sea-Level Highstand for the Last Interglacial

RSL records for the time period prior to the LGM are sparse, despite the shallow marine deposits and coral reefs of the last interglacial (Marine Isotopic Stage 5, MIS 5). The shallow

marine deposits are found at altitudes close to the present-day sea level in several tropical regions including the Red Sea, Peninsular Malaysia, southern Vietnam, and southern China. For example, a shallow marine depositional unit exists consistently at a depth of around 10 m below present sea level across the area of Hong Kong and within the Pearl River delta plain (Zong et al., 2009a). Earlier, the age of this unit was mistakenly attributed to a younger age because of the young age bias of radiocarbon dates, but it was later confirmed to be in the range around the MIS 5 (Yim et al., 1990). In Papua New Guinea (Yokoyama et al., 2001), Barbados (Bard et al., 1990), and Taiti (Dumas et al., 2006), the sea-level highstand is recorded from raised coral reefs or marine terraces.

Sea-Level Lowstand During the LGM

Earlier observations of the LGM sea level in the tropics have shown considerable uncertainty, in part because of the limitation of the preserved indicators and inadequate age determination. Similarly, earlier geophysical models have produced reconstructions of the LGM eustatic sea level with large uncertainties, ranging from -127 m as the upper limit estimate to -163 m as the lower limit estimate. By the end of the 1980s, the first reliable evidence of the LGM sea-level lowstand was reported from Barbados, where the local LGM RSL was recorded to be at approximately -120 m around 18 000 cal years BP, based on a deep core into the coral reef (Fairbanks, 1989). Subsequently, in Sunda Shelf, the local LGM RSL was observed at -115 m for a period between 21 000 and 19 000 cal years BP, based on only a few intertidal sediment samples (Hanebuth et al., 2000). The best record comes from the Bonaparte Gulf, north of Australia (Figure 6(a)), where the local LGM RSL was observed at -125 m, based on a significant

Figure 6 A relative sea-level curve (a) based on sea-level index points compiled from the Bonaparte Gulf, north Australia (Yokoyama et al., 2000), the Sunda Shelf (Hanebuth et al., 2000), and the Strait of Malacca (Geyh et al., 1979). A new record (b) from Singapore (Bird et al., 2010) shows that sea-level rise slowed down around 8000 years BP and accelerated around 7500 years BP.

number of intertidal and shallow marine sediment samples (Yokoyama et al., 2000). This altitude of the LGM RSL low stand is confirmed by new records from New Guinea and Barbados, and the low stand had started 26 000 cal years BP, ca. 5000 years earlier than previously assumed (Clark et al., 2009; Peltier and Fairbanks, 2006).

After the LGM sea-level data are adjusted using a glacio-hydro-isostatic formulation with Northern Hemisphere ice models and an Antarctic ice model that contributes 25 m to global sea level. The ice-volume-equivalent (eustatic) sea level during the LGM is placed between -130 and -135 m, corresponding to a volume of grounded ice in excess of the present volume by $52.5 \times 10^6 \text{ km}^3$ (Yokoyama et al., 2000). This finding is significant because it provides an accurate estimate of the total LGM ice volumes, which in turn can be used to constrain glaciologically based models. Furthermore, the results from the Bonaparte Gulf suggest RSL was relatively stable between 22 000 and 19 000 cal years BP at about -120 m (Figure 6(a)), although the oldest samples may have biased the ages upward by as much as several thousand years (Lambeck et al., 2002). The LGM sea-level lowstand was followed by a rapid rise of 10–15 m for a few hundreds of years, and a much slower rise around 19 000 cal years BP (Figure 6(a); Hanebuth et al., 2009; Yokoyama et al., 2000). It is noted that the data points for the LGM sea-level lowstand scatter around -120 m, possibly reflecting the differential hydro-isostatic loading at the different sites (Bassett et al., 2005).

During the LGM sea-level lowstand, much of the continental shelves in the tropics were exposed (Figure 7). As a result, Australia was linked up with New Guinea. A large land area emerged, joining the Malaysia Peninsula with major islands of Sumatra, Java, and Borneo, and separating the Indian Ocean from the South China Sea. Such an emergence of the extensive continental shelves significantly reduced the size of the maritime area between Australia and Southeast Asia, an important part of the Indo-Pacific Warm Pool. This in turn led to a reduction of moisture supply to the region and to some extent, the global system.

Late Glacial Rapid Sea-Level Rise

The first complete record of Late Glacial rapid sea-level rise comes from Barbados, where more than 30 coral (*A. palmata*) samples were dated and used in the reconstruction of RSL history (Fairbanks, 1989). This and other studies in Barbados and New Guinea have produced good RSL records that help clarify the dynamics of large ice sheets for the postglacial period. However, the reefs in these two locations overlie active subduction zones, where tectonic movements are large and often discontinuous. Thus, the apparent sea-level records from these two sites may be confounded by a complex tectonic component. Subsequently, a more reliable sea-level record was produced from a coral reef in Tahiti, a tectonically more stable site as it is far from plate boundaries (Bard et al., 1996). In Sunda Shelf, a number of sediment cores containing mangrove swamp deposits and intertidal sediment samples were analyzed and a local RSL was reconstructed (Hanebuth et al., 2000).

These sea-level records all point to the fact that the rate of rising sea level during the period between the LGM and the mid-Holocene has not been constant. In addition to the rise in

RSL of 10–15 m around 19 000 cal years BP (Yokoyama et al., 2000), two periods of accelerated rise in sea level have been observed, and named as melt water pulses (MWP) 1A and 1B (Figure 6(a)). According to the records from Sunda Shelf (Hanebuth et al., 2000), the first phase of accelerated sea-level rise started at 14 700 cal years BP and ended at 14 100 cal years BP, as RSL rose from approximately -95 to -80 m, in correspondence to the first cold reversal of the Bølling–Allerød period observed in Greenland ice cores. This accelerated rise in sea level was likely triggered by the rapid melting of the Antarctic ice sheet and ice sheets in Northern Hemisphere (Bassett et al., 2005). The second phase of accelerated sea-level rise is less well recorded, but is believed to have started soon after the Younger Drays cold period that ended at ca. 11 500 cal years BP (Bard et al., 2010). These two periods of accelerated sea-level rise are in full agreement with the ^{18}O records from deep-sea cores. Recently, a further change in the rate of sea-level rise has been recorded from Singapore, where sea-level rise slowed down from ca. 8000 cal years BP and accelerated again from ca. 7500 cal years BP (Figure 6(b); Bird et al., 2010). This punctuated sea-level rise has resulted in widespread marine transgression in many coastal lowlands of east and Southeast Asia (e.g., Hori et al., 2004; Zong et al., 2009b).

As a result of the rapid rise in sea level, the extensive continental shelves were submerged (Figure 7) and the Indo-Pacific Warm Pool was restored, leading to a significant change in the moisture supply and ecosystems across the region of east and southeast Asia (Griffiths et al., 2009). Similar changes also took place in the Gulf of Mexico, albeit to a lesser extent, and resulted in the restoration of moisture supply to southern Mexico and the surrounding areas.

Holocene Sea-Level Highstand

An RSL approximately 3 m higher than present-day RSL has been observed widely across the tropics (Pirazzoli, 1996). The reason for the occurrence of such a sea-level high-stand lies in the fact that the eustatic sea-level rise markedly slowed down in mid-Holocene, because the major ice sheets ceased to release meltwater to the oceans, combined with the hydro-isostatic processes that (1) water migrated away from far-field equatorial ocean basins in order to fill space vacated by collapsing forebulges at the periphery of previously glaciated regions, and/or (2) ocean loading at continental margins induced a levering of continents and a subsidence of offshore regions, resulting in the influx of water into the volume created by the subsidence and a sea-level fall at locations from these margins over major ocean basins (Mitrovica and Milne, 2002). However, differences in the timing and amplitude of the sea-level highstand remain, because it is still not clear whether meltwater release stopped abruptly in the mid-Holocene or whether there was a continued gradual release of meltwater during mid-Holocene and much of the late Holocene (Long, 2001).

The best record of mid-Holocene sea-level highstand comes from the Strait of Malacca, where mangrove and coastal peat deposits were surveyed and dated (Geyh et al., 1979). The results suggest that RSL reached its maximum height of approximately 4 m at about 6000–7000 cal years BP (Table 1) and afterward fell to the present level. The emergent Holocene

Figure 7 Continental shelves that were exposed at sea-level lowstand during the Last Glacial Maximum and submerged during postglacial sea-level rise and the Holocene sea-level highstand.

microatolls in Torres Strait indicate that during the past 6600 years the reefs have prograded seawards while sea level has fallen gradually from about 1 m above present (Woodroffe et al., 2000). On the Great Barrier Reef of Australia, a 1.7 m sea-level highstand is dated to about 6000 years ago (Larcombe et al., 1995). Along the south coast of China, a mid-Holocene sea-level highstand of approximately 1 m above present-day sea level has been recorded (Zong, 2004). Along the east coast of India, evidence from marine terraces of hermatypic corals and estuarine molluscs indicates a mid-Holocene sea-level highstand a few meters above the present-day sea level at ca. 7350 cal years BP (Banerjee, 2000). According to the times and heights of the mid-Holocene sea-level highstand recorded from tectonically stable sites of the tropics listed in

Table 1, a general pattern can be seen: the amplitude of mid-Holocene sea-level highstand decreases from its maximum at the equator toward mid-latitudes or intermediate-field sites where highstands are not recorded.

Records from the Marian Islands, Caroline Islands, Papua New Guinea, and the Taiwan Strait have all suggested mid-Holocene sea-level highstands of 1–3 m. But these records are less reliable because these areas have been subject to subduction tectonics. Furthermore, sea-level records from large estuaries are also less reliable due to local subsidence and sedimentary compaction. For example, no significant sea-level highstand was recorded from the Ganges delta (22–23°N; Islam and Tooley, 1999) and the Pearl and Han river deltas (22–24°N; Zong, 2004), while a mid-Holocene sea-level highstand is

Table 1 Examples of Mid-Holocene sea-level highstands recorded in tectonically stable sites of the tropics

Location	Latitude	Time (cal year BP)	Highstands (above sea level) (m)
South coast of China ^a	21–23° N	6200–6000	0.5–1.0
North coast of Vietnam ^b	20° N	5500	3.25
Thailand ^c	14° N	7000	~3

observed on the adjacent coasts. A number of studies have reported a second sea-level highstand occurring in the late Holocene (Table 1). However, the mechanism for this second highstand in far-field sites is neither known nor predicted by geophysical models. Therefore, the occurrence of this second highstand may be a result of local processes.

Conclusions

The Late Quaternary history of eustatic sea-level changes is revealed in multiple kinds of records from the tropics. After the sea-level highstand of the last interglacial, RSL in the tropics fell gradually to its lowest point at about 125 m below present and maintained this level during the period of the LGM between ca. 26 000 and 19 000 cal years BP. In the initial phase of deglaciation, the RSL rose rapidly by 10–15 m within a few hundred years, followed by a slow rise toward 15 000 cal years BP. Between ca. 15 000 and 10 000 cal years BP, RSL rose rapidly in two phases, corresponding to MWP 1A and MWP 1B, when a number of ice sheets on the Northern Hemisphere collapsed. From ca. 10 000 cal years BP, the RSL rose rapidly, but it slowed down at ca. 8000 cal years BP before continuing to rise from ca. 7500 cal years BP. By ca. 7000 cal years BP, the RSL reached to within a few meters above the present-day sea level, since which time it has gradually fallen to the present level.

Tectonics and Relative Sea-Level Change

Introduction

Records of relative sea-level (RSL) change archive the response of the Earth's surface to tectonic processes during the Quaternary, the most recent period of Earth history. Landforms or deposits marking former shorelines, termed strandlines, are widespread datums that can be measured more precisely than other types of landforms and deposits produced in response to tectonic processes. Although limited to coasts, sequences of successive strandlines are commonly better preserved over longer periods of time than other tectonic landforms. One third to one half of the Earth's marine coasts lie along or near tectonically active plate boundaries where the potential for large earthquakes threatens many population centers (Lajoie, 1986). Much of our understanding of tectonic processes over hundreds to hundreds of thousands of years has come from study of displacements (vertical components of tectonic deformation caused by faulting and local or regional folding) obtained through mapping and dating sequences of strandlines along tectonically active coasts. This improved understanding of the rates and scales of tectonic processes leads to better forecasting and mitigation of large earthquakes and related hazards – such as tsunamis and landslides – in inland as well as coastal regions worldwide.

RSL changes are a composite of real sea-level changes, which are vertical movements of the ocean's surface, and apparent sea-level changes, which are the inverse of vertical land-level changes along coasts (Lajoie, 1986; van de Plassche, 1986; Figure 1). Although sea level may rise and fall by meters over periods of hours during tidal cycles, storm surges, or tsunamis, most long-term evidence of real changes in mean sea level consists of erosional or depositional strandlines formed over periods of years to millennia. Real changes recorded by strandlines range from local changes of decimeters, for example, caused by changes in the configuration of the mouth of an estuary following a severe storm, to fluctuations of global sea level of 100–150 m caused by expansion and contraction of continental ice sheets over tens of thousands of years (Chappell et al., 1996; Milne and Shennan, 2007). Causes of apparent sea-level changes range from the slow (<0.01 mm year⁻¹) regional epeirogenic uplift of coasts over hundreds of thousands of years (Bloom, 1998; Murray-Wallace, 2007), to the meters of instantaneous, localized uplift of some coasts during the largest subduction-zone (a regional fault where one tectonic plate slides beneath another) earthquakes (Ota and Yamaguchi, 2004; Plafker, 1972). Quantifying the tectonic displacement (uplift or subsidence) of strandlines requires separating the apparent changes from the real changes in strandline records.

The degree to which real sea-level changes are conceptually distinct from apparent (inverse of land-level) changes is scale and time dependent. Over thousands to tens of thousands of years Earth's crust and underlying mantle adjust to isostatic loading from continental ice sheets and global increases in

ocean volume, and over hundreds of thousands to millions of years to lithosphere isostatic loading. Changes in the volume of water in the ocean cause real sea level to rise or fall and over thousands of years ocean volume responds in complex ways to changes in the shape of ocean basins that are driven by slow adjustments in the crust and mantle (Milne and Shennan, 2007; Woodroffe, 2007). From this long-term perspective, all sea-level changes have an apparent component; even strandlines on the most tectonically stable coasts formed partly as a result of apparent sea-level changes.

The areal extent and scale of RSL changes, and the precision with which former sea levels can be measured from strandlines, depend on time span and sea-level history. For this reason, different types of information about tectonic processes are derived from different types of strandlines of differing age. Small apparent sea-level changes of a few meters or less are much more easily identified during the late Holocene (<6 ka, <6000 years old) when real sea-level changes were <1 – 2 m on many coasts than during the early Holocene (12–6 ka) when global sea level was rising rapidly (>10 mm year⁻¹) due to melting of continental ice sheets (Figure 1(b)). Strandlines of the past few hundred years in unusual settings, such as the coralline coasts of Sumatra (Figures 2 and 3), can record centimeters of apparent change in sea level over decades because the amplitude of real sea-level changes over this period has been small. Pleistocene (1.6 My to 12 ka) strandlines record highstands – and less commonly lowstands – of global sea level (Figures 4 and 5), but because they average sea-level position over the hundreds to thousands of years over which they formed, only rarely can they be used to identify sea-level changes of less than a few meters (Chappell et al., 1996; Muhs et al., 2004). Nevertheless, Pleistocene strandlines provide an invaluable measure of the net effect of long-term tectonic processes along tens to hundreds of kilometers of coast over tens of thousands to hundreds of thousands of years.

Strandlines formed on different types of coasts, and at different elevations within the elevational range of tides, have differing degrees of uncertainty, termed indicative meaning, in their relation to mean sea level over their time period of formation (van de Plassche, 1986). For example, the relation of the landward edge of a 120-ka, gravelly, marine terrace to its former mean sea level may have an indicative meaning of several meters, whereas the indicative meaning of the landward edge of a buried tidal marsh to its former mean sea level may be a few tens of centimeters or less. Additional uncertainty in the position of former sea levels depends on the degree of preservation of strandline deposits, landforms, and included fossils, as well as on the level of detail of strandline study. Significant increases in the precision of strandline measurement in the past quarter century have come about through improved understanding of shoreline processes and more rigorous evaluation of errors in strandline indicative meanings.

The most significant advances in understanding tectonic processes through study of strandline records have come

Figure 1 Relative, apparent, and real sea-level changes; (a) late Pleistocene; (b) Holocene. Relative sea-level (RSL) changes are the sum of apparent and real changes. Real sea-level change is the change in the height of the ocean surface adjacent to a shoreline. Apparent sea-level change is the inverse of displacement (D), or the vertical component of tectonic deformation of a shoreline. Displacement is the difference between the present elevation of a strandline (E) and its original elevation (e). The rate of displacement (assumed constant here) is the displacement divided by age (D/A ; ka, 1000 years before AD 1950). Modified from Lajoie KR (1986) Coastal tectonics. In: Wallace RE (ed.) *Active Tectonics*, pp. 95–124. Washington, DC: National Academy of Sciences, National Academy Press. In (b), on many uplifting coasts relative sea level rose until about 6 ka and then fell as uplift rates exceeded real sea-level rise. This produced an early Holocene transgression of the sea followed by a late Holocene regression.

from new and improved methods of dating strandlines (Muhs et al., 2004). Accelerator mass spectrometer ^{14}C dating of samples with less than a thousandth of the carbon formerly needed for dating Holocene strandlines has increased the number of potentially datable strandline samples more than a thousand fold. Mass spectrometric uranium-series dating of well-preserved fossil corals from drill cores on the tectonically stable island of Barbados in the Caribbean has yielded a Pleistocene and Holocene sea-level history that has been used to separate real from apparent sea-level changes worldwide (Bard et al, 1990; Woodroffe, 2007). In the past decade and a half, Holocene as well as Pleistocene strandlines on many coasts have been dated with thermoluminescence and optically stimulated luminescence methods, and more recently with several methods of cosmogenic nuclide dating (^{10}Be , ^{26}Al , ^{36}Cl) using accelerator mass spectrometers (Figure 6). Amino-acid racemization ratios on fossil molluscs have also been an important tool for correlation of Pleistocene strandlines (Figure 7; Muhs et al., 2004; Murray-Wallace, 2007). Some of the highest resolution sea-level studies use uranium-series ages with analytical errors of only a few years to identify centimeter-scale sea-level changes recorded by coral microatolls above the subduction-zone megathrust (plate-boundary fault) of western Sumatra that produced the devastating Indian Ocean tsunami of 2004 (Figures 2 and 3).

Tectonic Processes and Rates

Earthquake Deformation Cycle

For over a century, the accumulation and release of tectonic strain along faults in the shallow (<15 km deep), brittle crust of the Earth has been modeled by the earthquake deformation cycle (Sholtz, 2002; Yeats et al., 1997; Figures 8 and 9). Constant tectonic stress accumulates as strain in rock near a fault until the frictional strength of the fault is exceeded and the fault slips during an earthquake. In the classic model of the cycle, this coseismic slip along the fault is just enough to release all the strain stored in rock on either side of the fault. The instantaneous coseismic deformation (slip on a fault expressed as faulting or folding at the surface) is greatest along the fault plane and in rock adjacent to the fault due to release of accumulated strain, which decreases exponentially away from the fault. Geodetic and tidal observations near active faults in Japan, Chile, and other areas before and after large earthquakes show that the amount and direction of coseismic deformation at various distances from a fault are approximately the opposite of the deformation caused by strain accumulation prior to the earthquake. For example, coasts above subduction-zone megathrusts slowly rise or fall (recording displacement from strain accumulation above the megathrust) for hundreds of years between great (M8-9, magnitude 8 or 9) earthquakes

Figure 2 Coral microatoll growth in response to RSL changes above the western Sumatran subduction zone: heavy green rings, living coral bands; brown rings, dead coral bands that grew under present sea level; pink and thin green rings, dead bands that grew under older sea levels; graph at left shows trend of sea level (SL) with time (T). (a) Coral grows unimpeded with hemispherical shape below growth-limit sea level. (b) When coral reaches growth-limit level, coral head grows laterally. (c) If sea level drops to lower level, exposed coral dies, but lateral growth continues below growth-limit level to form coral head with 'hat' morphology. (d) If sea level rises to higher level, coral head grows upward and outward to form 'cup' morphology, but sudden (coseismic) sea-level rise cannot be distinguished from a gradual (interseismic) rise (dashed queried line). (e) If sea level rises to higher level reached by coral head, head grows laterally from both outer and inner edges covering older coral in center of head. (f) If sea level rises more rapidly than coral grows upward, coral will not record sea-level changes. (g) Cross-section through hypothetical coral head that records sea-level changes shown in graph at left; queried lines show alternative sea-level history. Modified from Zachariassen J, Sieh K, Taylor FW, and Hantoro WS (2000) Modern vertical deformation above the Sumatran subduction zone: Paleogeodetic insights from coral microatolls. *Bulletin of the Seismological Society of America* 90: 897–913.

on the megathrust, and then are suddenly jerked downward or upward, respectively, by a similar amount during earthquakes (Figure 9; Satake and Atwater, 2007). Following each earthquake, strain again accumulates during the interseismic period between the previous and the next earthquake on the fault.

Instrumental and tidal observations of the past century near tectonically active coasts show much more complicated patterns of deformation than implied by the classic model of the earthquake cycle (Briggs et al., 2008; Ota and Yamaguchi, 2004; Pirazzoli, 1996; Sholtz, 2002; Wang, 2007). In some cases, strain accumulation accelerates during both the pre-seismic period, just prior to the earthquake, and the postseismic period following it (Figure 9(c)). At some coastal sites, the amount of pre-seismic or postseismic displacement may be as

much as or even exceed the coseismic slip, and on most faults, displacement commonly varies from cycle to cycle. In the case of some plate-boundary faults that extend to depths well below the brittle shallow crust of the Earth, 'slow' (occurring over hours to years) earthquakes may release huge amounts of energy which may be recorded by postseismic or interseismic deformation above deep faults. Beneath coastal south-central Chile, continuing small adjustments of the deep crust and mantle are a response to megathrust slip during the M9.5 earthquake of 1960. Most importantly for studies of tectonically displaced strandlines, all of the pre-faulting strain may not be recovered during large earthquakes. The small but permanent unrecovered strain following successive earthquakes may accumulate in complex patterns that are recorded by uplifted or subsided strandlines.

Figure 3 Photographs and corresponding line drawings of uplifted *Porites* coral microatolls on the west coast of Sumatra. (a) An uplifted hemispherical *Porites* head that records the new, postearthquake highest level of survival (HLS) as the top of a thin living strip at its base. The uppermost, exposed portion of the microatoll is dead and covered with algae. (b) A *Porites* microatoll that records multiple uplift events. Uplift of ~11 cm during the December 2004 earthquake resulted in the elevation difference between the uppermost living coral before and after the earthquake. The more brightly colored area beneath the pre-March 2005 HLS is outward growth during the period between the December 2004 and March 2005 earthquakes. During the March earthquake the coral was uplifted another ~65 cm, causing the head to be lifted entirely out of the water into a position too high to record post-March 2005 HLS. Reproduced from Briggs RW, Sieh K, Meltzner AJ, et al. (2006) Deformation and slip along the Sunda megathrust in the great 2005 Nias-Simeulue earthquake. *Science* 311: 1897–1901.

Two important end-member models of the earthquake cycle allow prediction of the time or size of the next earthquake (Figure 8; Burbank and Anderson, 2001; Yeats et al., 1997). In the classic periodic cycle model, the frictional strength of the fault, the stress drop during slip on the fault, and the time till the next earthquake are the same during each cycle. Thus, both the time and magnitude (amount of energy released) of the next earthquake can be predicted. In the time-predictable model, earthquakes occur whenever a constant stress level on the fault is reached, but the amount of stress drop and the slip are unpredictable. If interseismic strain accumulation is constant and the amount of slip in the previous earthquake is known, the time of the next earthquake – but not its slip – can be predicted. In the slip-predictable model, slip on a fault during an earthquake is assumed to stop when the stress has dropped to a constant level. If the time since the previous earthquake is known, the amount of slip during the next earthquake at any given time can be predicted, but not the time of the next earthquake.

The nucleation and propagation of earthquake ruptures along fault planes, especially on large plate-boundary faults, is far more complex than implied by such simple models (Wang, 2007). As shown in many studies of modern earthquakes, deep earth structure, laboratory studies of rock, geologic mapping, and historical studies of preinstrumental large earthquakes, the strength and topography of fault planes varies greatly along fault strike as well as with depth (Figures 10 and 11; Sholtz, 2002). Cumulative slip along fault planes over many earthquake cycles produces changes in fault plane properties over time. Despite the popularity of models of uniform fault slip during successive earthquakes, such changes in fault plane properties imply that the slip during successive earthquakes at the same location on most faults, as well as along the length of faults during a single earthquake, will vary. Furthermore, slip on some large faults alters the stress fields on nearby – and occasionally distant – faults and so affects the timing and magnitude of future earthquakes on the faults. Such complexity in the amounts and rates of fault

Figure 4 Hypothetical strandlines of uplifted and subsided coasts and their relations with highstands and lowstands of real sea level derived from the oxygen-isotope record from deep-sea foraminifers. Uplifted reef or wave-cut terraces approximately correspond with highstands (interglacial periods); subsided coral reefs correspond with lowstands (glacial periods) on some tropical coasts with high uplift rates. Modified from Muhs DR, Wehmler JF, Simmons KR, and York LL (2004) Quaternary sea-level history of the United States. In: Gillespie AR, Porter SC, and Atwater BF (eds.) *The Quaternary Period in the United States*, pp. 147–183. Amsterdam: Elsevier.

Figure 5 View of marine terraces on the west coast of San Clemente Island, about 80 km northwest of San Diego, California, looking northward. See references in Muhs et al. (2004). Photograph by Dan Muhs.

slip at depth is reflected in the variability in displacement rates recorded by strandlines above faults and folds (Figure 12; Burbank and Anderson, 2001; Merritts, 1996; Ota and Yamaguchi, 2004). In Chile, the M9.5 1960 earthquake was larger than would have been predicted from historical records of Chilean earthquakes and plate convergence rates (Cisternas et al., 2005), whereas modeling of measurements of coastal uplift and subsidence during the M8.8 2010 earthquake farther

north suggest that it released most fault strain accumulated since the previous earthquake. As a result of such complex fault behavior, precise prediction of the time or magnitude of future earthquakes is not a practical goal (Figure 8(d)).

Volcanic Processes

Strandlines record extremely high rates of uplift or subsidence on the flanks of some active volcanoes. For example, on the island of Iwo Jima in the western Pacific, uplift rates vary between 100 and 800 mm year⁻¹ and average about 200 mm year⁻¹ for the past 800 years (Kaizuka, 1992). Vertical rates of volcanic deformation of more than 50 mm year⁻¹ also have been measured for short periods on several coasts, but are highly localized in time (less than a few decades) and space (generally within kilometers of volcanoes; Lajoie, 1986; McCalpin, 2009, ch. 4). Over periods of hundreds to hundreds of thousands of years, displacement rates associated with volcanic and other processes of magma generation – such as migrating hotspots like the Hawaiian Islands and the Yellowstone region of Idaho – are commonly at least an order of magnitude lower (<2–5 mm year⁻¹; Lajoie, 1986; Muhs et al., 2004).

Epeirogenic and Isostatic Tectonic Processes

Bloom (1998) distinguishes epeirogeny, or regional scale, vertical tectonic deformation of low amplitude relative to its

Figure 6 Marine terrace uplift and folding on the Arauco Peninsula of south-central Chile. (a) Surface uplift rates for the Cañete, Esperanza, and Nochas terrace surfaces and a maximum–minimum profile of peninsula topographic elevations parallel to the coast (gray shading). MIS indicates the marine isotope stage with which each terrace is correlated based on cosmogenic nuclide dating. (b) Elevation of shoreline angles (the upper edges of marine terraces) for the three main marine terraces (dated by cosmogenic methods as shown) from the main fold in the center of the peninsula (marked at bottom of (a)) and polynomial curves fitted to the elevations. (c) Shortening (amount of lateral fold compression) rates for the three marine terraces estimated from the curves of (b). Errors on the fold shortening rates are too large to determine whether or not shortening has decreased or remained constant over the past few hundred thousand years. Reproduced from Melnick D, Bookhagen B, Strecker MR, and Echtler HP (2009) Segmentation of megathrust rupture from fore-arc deformation patterns over hundreds to millions of years, Arauco peninsula, Chile. *Journal of Geophysical Research* 114: B01407. <http://dx.doi.org/10.1029/2008JB005788>.

wavelength that cannot be measured in a single outcrop, from orogeny, the tectonic processes that produce deformation of shorter wavelengths in mountain belts. During the seconds to minutes of earthquake faulting and folding in mountain belts, the crust, and mantle deform elastically. Over the decades to thousands of years of complete earthquake cycles or the glacioisostatic subsidence and uplift caused by ice-sheet expansion and retreat, the crust is strong and elastic whereas the

mantle is weak and ductile. Over millions of years, the topographic balance maintained by light, rigid crust floating on much denser, ductile mantle ensures that epeirogenic uplift and subsidence proceed at rates at least several orders of magnitude lower than deformation rates within mountain belts. Epeirogenic and isostatic processes are only briefly mentioned in this overview because they reflect surface and subsurface loading of the crust and flow of mantle material rather than

Figure 7 Coast-parallel pattern of displacement of Pleistocene strandlines in relation to the bathymetry of the 1200-m-high Nazca Ridge, which is subducting beneath this part of Peru. Symbols mark locations where elevations of marine terraces of different relative age were measured on coast-perpendicular transects. Solid lines connecting symbols show correlations of mapped terraces; dashed lines are tentative correlations. Amino acid ratios (mean ratio for each terrace shown under terrace correlation lines) on mollusks in terrace deposits show terrace relative ages. Terraces are displaced in proportion to the bathymetry of the ridge being subducted beneath them. Modified from Hsu JT (1992) Quaternary uplift of the Peruvian coast related to the subduction of the Nazca Ridge: 13.5 to 15.6 degrees south latitude. In: Ota Y, Nelson AR, and Berryman KR (eds.) Impacts of Tectonics on Quaternary Coastal Evolution. *Quaternary International* 15/16: 87–97.

Figure 8 (a) Periodic model of the earthquake deformation cycle in which stress levels before and after an earthquake are known. In the periodic model the time to the next earthquake and the fault slip during the earthquake are predictable. (b) Time-predictable model of cycle where fault slip occurs at a constant level of stress. (c) Slip-predictable model where stress drops to a constant level during an earthquake. (d) Time-and-slip-unpredictable model of the earthquake cycle with changing rates of stress accumulation and release that result in variable slip rates. sustained, primary tectonic processes, such as subduction and rifting, caused by horizontal motions of tectonic plates.

Glacioisostasy has produced the highest rates of regional strandline displacement (90 mm year^{-1}) yet measured. Strandlines near the centers of continental glaciation in North America

and Europe record hundreds of meters of postglacial uplift over a few thousand years in areas tens to hundreds of kilometers wide. Measurement and dating of the rapid uplift and subsidence of strandlines in glaciated areas yield information about the rigidity of the underlying mantle that helps us understand tectonic

Figure 9 Schematic diagram showing deformation associated with a subduction-zone thrust fault beneath a coast during an earthquake cycle: (a) interseismic strain accumulation; (b) coseismic fault slip and strain release. Components of RSL change during two earthquake cycles: (c) land-level (strandline) displacement; (d) apparent sea-level changes; (e) real sea-level rise; (f) RSL history during two cycles. Preseismic and postseismic parts of the cycle (c) immediately precede and follow instantaneous coseismic fault displacement. In (a) and (b), the red solid and dashed lines mark the fault boundary between the upper and subducting plates; the red dashed line is a transition zone between locked (solid line) and plastically deforming parts of the plate boundary. Shading shows the relative amount of coastal uplift and subsidence of the upper plate during the interseismic and coseismic parts of the earthquake cycle. Shaded band in (f) shows typical uncertainty in some of the more precise sea-level indicators associated with late Holocene strandlines. The typical ± 0.5 -m uncertainty in late Holocene sea-level indicators makes identification of displacements of < 0.5 m difficult. Modified from Nelson AR, Shennan I, Long AJ (1996) Identifying coseismic subsidence in tidal-wetland stratigraphic sequences at the Cascadia subduction zone of western North America. *Journal of Geophysical Research* 101: 6115–6135.

Figure 10 Coseismic and interseismic slip history for a transect perpendicular to the subduction-zone megathrust beneath western Sumatra developed from studies of twentieth-century coral microatolls (Figures 2 and 3). The dark areas represent the modeled amounts of coseismic slip during an earthquake in 1935 and an inferred slow earthquake in 1962. Lighter shading shows interseismic slip for labeled periods between earthquakes. The shallower and deeper parts of the fault have slipped continuously, whereas the fault at intermediate depths sticks and then slips during large earthquakes. Such patterns of coseismic and interseismic slip on the fault hint at the complex nature of slip on the fault planes of plate-boundary faults, even within a single cross-section perpendicular to one fault. Modified from Natawidjaja DH, Sieh K, Ward SN, et al. (2004) Paleogeodetic records of seismic and aseismic subduction from central Sumatran microatolls, Indonesia. *Journal of Geophysical Research* 109: B04306. <http://dx.doi.org/10.1029/2003>.

Figure 11 Comparison of the moment (energy released during an earthquake) released by earthquakes in 2007 with the moment deficit (unreleased strain) accumulated since the earthquakes in 1797 and 1833 along the western Sumatran subduction zone. Brown and pink lines are the upper and lower bounds of estimated moment release during the 1833 and 1797 earthquakes based on models using geodetic and coral-microatoll data. The red curve shows the accumulated moment deficit since the last great earthquake derived from modeling strain accumulation between great earthquakes. Modified from Konca AO, Avouac J-P, Sladen A, et al. (2008) Partial rupture of a locked patch of the Sumatra megathrust during the 2007 earthquake sequence. *Nature* 456: 631–635.

processes in unglaciated as well as glaciated regions (Milne and Shennan, 2007). The rapid decrease in vertical crustal stress that accompanies land uplift following deglaciation (ice-sheet retreat) has triggered earthquakes on faults in deglaciated areas of Canada and Scandinavia. As part of the redistribution of mantle material during deglaciation, coasts well beyond uplifting glaciated areas may subside due to a collapsing glacial forebulge.

Other regional epeirogenic processes that displace strandlines over hundreds to thousands of years include the loading of continental shelves with water (hydroisostasy; Milne and Shennan, 2007; Pirazzoli, 1996; Stewart and Vita-Finzi, 1998). Loading during deglaciation is primarily a response to an increase in ocean volume as a result of ice-sheet melting. The loading is accompanied by landward migration of viscous mantle material, which may uplift strandlines without any reduction in ocean volume (Murray-Wallace, 2007). Although commonly more localized (near major river deltas) than hydroisostasy, sediment loading on continental shelves over thousands of years also displaces strandlines.

Strandline Records of Deformation

Strandlines preserved over later Pleistocene (400–12 ka) and Holocene (<12 ka) timeframes record differing types and rates of real and apparent sea-level changes.

Pleistocene

Most Pleistocene standlines consist of emergent (uplifted) shoreline platforms formed during highstands of sea level on tectonically rising coasts when global ice volumes were low (Chappell et al., 1996; Woodroffe, 2007; Figure 1). Given sufficient rates of uplift ($>0.1 \text{ mm year}^{-1}$), successively higher wave-cut platforms, commonly 0.1–10 km wide, form a stair-step pattern along emergent coasts (Figure 4). Platforms may be erosional (high-wave-energy coasts; Figures 5 and 6) or constructional (low-energy coasts, such as reefs in tropical waters; Figure 12). Erosional platforms are typically veneered with several meters of sandy to gravelly, shallow-water sediment, occasionally containing datable fossils such as molluscs or corals. On most coasts, subaerial erosion makes strandlines older than 400 ka indistinct and difficult to date; where uplift rates are very high ($>4 \text{ mm year}^{-1}$) erosion typically removes strandlines older than 120 ka (Lajoie, 1986). Strandlines formed during global highstands are also present on slowly rising ($<0.1 \text{ mm year}^{-1}$) or stable coasts, but are difficult to identify and date (Muhs et al., 2004).

Strandlines marking Pleistocene lowstands of sea level are less well preserved and much less accessible than those marking highstands. Lowstand strandlines were commonly eroded during the transgressions and regressions to and from sea-level highstands, or they lie buried in subsided basins. Thus, most studies of lowstand strandlines are limited to coasts where

Figure 12 Reconstructed uplift history for central Rendova Island, New Georgia Group, southwestern Pacific, showing highly variable rates of uplift and subsidence for the past 270 000 years. The Holocene reef (6 ka) reaches 20 m above sea level and has uplifted $\sim 3 \text{ mm year}^{-1}$ at this location. Drilling penetrated the Last Glacial Maximum ($\sim 21 \text{ ka}$) at a depth of $\sim 55 \text{ m}$ below sea level (BSL) showing that the 3 mm year^{-1} rate dates from at least 21 ka. The reefs uphill from the 20-m Holocene reef surface are very weathered and are much older than 40–130 ka. Therefore, uplift that raised the Holocene reef to 20 m above sea level and the 21 ka reef to 55 m below sea level began recently, probably after $\sim 50 \text{ ka}$. Prior to the uplift, subsidence is required to account for the older reefs beneath the 21-ka reef and to explain the absence of 40–130-ka reefs uphill from the Holocene reef. The older reefs that are now at 50–300 m above sea level rose during a period of uplift prior to the subsidence. Modified from Taylor FW, Mann P, Bevis MG, et al. (2005) Rapid forearc uplift and subsidence caused by impinging bathymetric features: Examples from the New Hebrides and Solomon arcs. *Tectonics* 24: TC6005. <http://dx.doi.org/1029/2004TC001650>.

uplift rates are high enough to have raised lowstand features above present sea level ($>0.3\text{--}1.0 \text{ mm year}^{-1}$), or where transects of drill cores access coral reefs formed during both high and lowstands of sea level (Figures 4 and 12; Bard et al., 1990). For example, in deep valleys cut into rapidly uplifting terraces of the Huon Peninsula of Papua New Guinea, small deltas marking lowstands of sea level are protected from erosion by coral reefs deposited during higher sea levels (Chappell et al., 1996). Although geophysical methods such as side-scan sonar allow detailed mapping of submerged strandlines (McCalpin, 2009, ch. 2B), such methods are costly and dating the strandlines is difficult. In Hawaii, where rates of subsidence are particularly high, lowstand strandlines as old as 475 ka have been dated by uranium-series methods (Muhs et al., 2004).

Dating of Pleistocene strandlines over the past three decades has been improved through comparisons with the oxygen-isotope record from marine cores and the RSL records of emergent coral-reef strandlines on New Guinea and Barbados (Figure 4; Woodroffe, 2007). Assuming a constant coastal uplift rate, subtraction of the amount of uplift from elevations of strandlines well dated by uranium-series methods on fossil corals yields paleosea-level curves extending back to about 300 ka. On uplifting coasts, where only one or two strandlines have been dated by numerical methods, assumption of an average uplift rate and correlation of the elevations of strandlines of unknown age with the New Guinea and Barbados records yields inferred ages for undated terraces (Figure 12).

Figure 13 Late Holocene strandlines along the central east coast of Isla Mocha, a 12-km-long island 30 km off the coast of Chile above the Chilean subduction zone (latitude 38° S). Some of the strandlines were uplifted suddenly during great earthquakes on the Chilean subduction zone, whereas others were probably built by storm waves during periods of rapid interseismic uplift (Figure 14). Reproduced from Nelson AR and Manley WF (1992) Holocene coseismic and aseismic uplift of Isla Mocha, south-central Chile. In: Ota Y, Nelson AR, and Berryman KR (eds.) *Impacts of Tectonics on Quaternary Coastal Evolution. Quaternary International* 15/16: 61–76.

Recent dating of Pleistocene strandlines in North America and elsewhere shows significant differences in the length and timing of some highstands (Muhs et al., 2004).

Regional patterns of Pleistocene strandline displacement commonly reflect primary tectonic processes related to

horizontal plate motions, whereas local patterns reflect deformation on secondary faults and folds in the shallow crust, which respond to more localized stresses (Lajoie, 1986). Regional patterns are most clearly shown by maps of displacement isobases, which generally mimic topographic contours,

Figure 14 RSL history of Isla Mocha (Figure 13). Radiocarbon ages on shells from uplifted strandlines suggest an increasing rate of uplift in the late Holocene. The dashed line outlines an envelope, encompassing the most reliable ^{14}C ages, of RSL change since 6 ka. Real sea-level history, which is poorly known in this region, must be subtracted from the envelope to determine changes in uplift rate. Coseismic uplift of the island in 1835 and 1960 suggests that late Holocene uplift is the result of similar great earthquakes during the past few thousand years. However, the extremely high rate of interseismic uplift since at least 1965 (70 mm year^{-1}) suggests that some raised strandlines ringing the island rose during interseismic as well as coseismic parts of the earthquake cycle. Horizontal arrows in boxes mark shell samples that are probably reworked from older strandlines. Small vertical arrows show samples that were probably deposited $>1 \text{ m}$ below a contemporaneous shoreline. Lithologies of strandlines suggest that some are erosional and others depositional. Modified from Nelson AR and Manley WF (1992) Holocene coseismic and aseismic uplift of Isla Mocha, south-central Chile. In: Ota Y, Nelson AR, and Berryman KR (eds.) Impacts of Tectonics on Quaternary Coastal Evolution. *Quaternary International* 15/16: 61–76.

Figure 15 Genroku marine terrace at Mera on the Boso Peninsula of Japan uplifted 4.8 and 1.5 m during the great Kanto earthquakes of 1703 and 1923, respectively (Matsuda et al., 1978). Houses in background are on a higher terrace estimated from the average uplift rate to date from about 3.5 ka.

Figure 16 Simplified models of land-level change in estuary tidal wetlands during two earthquake cycles above subduction zones of southwest Washington and south-central Chile. Heavy line shows inferred land-level change relative to sea level. In (a), buried coastal forest and wetland soils (1 and 2) are quickly buried by many decimeters of tidal mud and sand following coseismic subsidence due to modest postseismic recovery and slowly rising sea level. This process creates stacks of well-preserved buried soils that can be dated by radiocarbon. In (b), similar subsidence, largely complete postseismic recovery, and slowly falling sea level result in minimal burial and later erosion of tidal marsh soils; buried soils are not preserved.

but require areally extensive strandline or other paleoelevation measurements. Faults, folds, and broad regional tilting resulting from fault slip near plate boundaries are illustrated by isobase maps of coastal areas of Japan, Taiwan, New Zealand, and Chile. More commonly, sequences of strandlines illustrate progressive folding or faulting along coast-parallel, vertical planes that transect active folds and faults (Keller and Pinter, 2002; Kaizuka, 1992; Stewart and Vita-Finzi, 1998). For example, regionally deformed marine terraces along the coasts of southern Peru and south-central Chile record folding over the

past half million years caused by oblique subduction of the Nazca oceanic ridge beneath Peru and the northward movement of a sliver of Chilean continental crust, respectively (Figures 6 and 7).

Rates of uplift measured from Pleistocene strandlines rarely exceed 2 mm year^{-1} , even near plate boundaries with the highest rates of slip. Regional isostatic adjustment of the crust beneath more rapidly uplifting coasts apparently prevents higher Pleistocene rates (Lajoie, 1986). Graphical comparisons of Pleistocene strandline elevations on many emergent coasts

with the well-dated New Guinea strandlines show that assumptions of constant uplift are reasonable for many sequences in the range 100–500 ka (Lajoie, 1986); direct evidence of constant rates in New Guinea includes converging coast-parallel strandline profiles that show progressive tilting at a constant rate since 125 ka (Burbank and Anderson, 2001). Exceptionally high rates of Pleistocene uplift of 8 mm year^{-1} followed by rapid subsidence measured from reef corals in the Solomon Islands of the southwest Pacific can be explained by subduction of a seamount over the past 200 000 years (Figure 12). The high rates of subsidence as well as uplift measured from some Holocene strandlines, tide gauges, and by global positioning systems are short-term rates that include only parts of earthquake cycles and are averaged over much longer Pleistocene time spans. For example, on the Muroto Peninsula in Shikoku, Japan, uplift rates for the 120- and 6-ka strandlines are about 2 mm year^{-1} , but episodic uplift of the past 300 years was six times as high and tide-gauge data indicate subsidence during part of this period (Ota and Yamaguchi, 2004; Sholtz, 2002). Similarly, parts of the Oregon coast are currently subsiding at rates three times the uplift rates of 0.3 mm year^{-1} recorded by nearby 125-ka marine terraces.

Holocene

The Holocene timeframe includes an early Holocene period of rapidly rising sea level (12 ka to about 6 ka on many coasts) and a following, late Holocene period of slowly rising, stable, or slowly falling sea level, depending on how glacioisostatic adjustments affect real sea level in different parts of the globe (Figure 1; Milne and Shennan, 2007; Murray-Wallace, 2007; Pirazzoli, 1996). Early Holocene strandlines provide little information about tectonic processes because most were eroded and submerged by a rapidly rising sea and are now largely inaccessible. In contrast, late Holocene strandlines provide insight into tectonic processes at a level of detail not possible with Pleistocene strandlines. This is especially true of strandlines formed during the past 2000 years when real sea-level changes on most coasts were $< \pm 2 \text{ m}$. For this reason, RSL changes during the past 2000 years are largely tectonic (apparent) changes (Burbank and Anderson, 2001; Lajoie, 1986).

Rapidly uplifting ($> 1\text{--}2 \text{ mm year}^{-1}$) late Holocene strandline sequences yield some of the most detailed archives of large plate-boundary earthquakes. Historically uplifted marine terraces in Japan, Alaska, and New Zealand are the basis for the time-predictable and slip-predictable models of earthquake recurrence discussed above (Matsuda et al., 1978; Shimazaki and Nakata, 1980). These widely influential models have been used to develop earthquake histories from Holocene marine terraces 1–15 m above sea level on tectonically active coasts and even to forecast future earthquakes at well-dated sites (Figures 13, 14, and 15; Merritts, 1996; Ota and Yamaguchi, 2004; Stewart and Vita-Finzi, 1998).

As attractive as the models of coseismic displacement are, no strandline records fit the models exactly and the complexities of coastal and earthquake-cycle processes caution against using the models to forecast future coseismic strandline displacement. First, most emergent Holocene strandlines record localized displacement related to folding or faulting above thrust faults in the upper few kilometers of crust. For this

reason, most uplifted strandlines record displacement on local rather than regional plate-boundary faults, usually in compressive tectonic settings (Lajoie, 1986; Melnick et al., 2009; Nelson and Manley, 1992; Ota and Yamaguchi, 2004; Plafker, 1972). Because local folds and faults respond only intermittently to regional stresses, it is unlikely that strandlines above a shallow fold or fault will record all large earthquakes on a deeper plate-boundary fault, or that strandline spacing will reflect the relative amount of slip on plate-boundary faults over either Pleistocene or Holocene timeframes (Briggs et al., 2008; Burbank and Anderson, 2001). Secondly, geodetic and tide-gauge data from Japan, Alaska, Chile, Indonesia, and other coasts near plate-boundary faults show that RSL may rise or fall at rapid nonlinear rates during interseismic parts of the earthquake cycle (Wang, 2007). If major storms create distinct but short-lived shorelines on such rapidly rising coasts, storm shorelines could easily be mistaken for strandlines formed by meters of coseismic uplift (Figures 13 and 14).

Finally, even strandlines that are distinct from higher and lower strandlines may span multiple earthquake cycles. For example, on the Boso and Muroto peninsulas of Japan, the lowest marine terrace was uplifted during two or three closely spaced historical earthquakes rather than during a single large earthquake (Figure 15; Ota and Yamaguchi, 2004; Sholtz, 2002). Even above subduction-zone megathrusts

Figure 17 Section of sediment in a tidal channel at Alsea Bay, on the central Oregon coast, showing tidal-marsh A horizons formed on tidal mud prior to coastal subsidence during great earthquakes about 300 (AD 1700) and 800 years ago, and the A horizon of the present marsh. Sandy beds deposited by tsunamis immediately overlie the two older A horizons. Scale in decimeters.

where shallow, localized faults are apparently inactive, such as on Nias Island off western Sumatra, the modest (<11 m) uplift of mid-Holocene terraces suggests that none record uplift during only a single earthquake. The mismatch between the 0–2.9 m of uplift of the island during the M8.7 2005 earthquake and the 1.5 to -0.2 mm year $^{-1}$ net rates of uplift measured from mid-Holocene terraces show that strain accumulation on this part of the megathrust is elastic with largely complete recovery of coseismic uplift during interseismic periods (Briggs et al., 2008).

In contrast to most emergent late Holocene strandlines, the most widely studied submergent strandlines record regional (rather than local) deformation during the largest known earthquakes. In the Pacific Northwest of the U.S. and Canada, Alaska, Chile, and Japan, tidal wetland soil buried by tidal mud and sand testify to repeated coseismic subsidence of wetlands

during great earthquakes on underlying subduction-zone megathrusts many hundreds of kilometers long (Figure 16; Atwater and Hemphill-Haley, 1997; Carver and Plafker, 2008; Cisternas et al., 2005; McCalpin, 2009, ch. 5; Satake and Atwater, 2007; Sawai et al., 2004; Shennan and Hamilton, 2006). The modern analogs for such records of coseismic subsidence are regions of 80 000 and 110 000 km 2 , in Chile and Alaska, respectively, that subsided 1–2 m during M9 earthquakes in the 1960s (Plafker, 1972). Study of such decimeter-to-meter-scale records of regional subsidence requires easily dated strandlines with precise indicative meanings in settings favorable for strandline preservation. For example, the well-preserved stacks of wetland soils interbedded with tidal mud beneath the modern tidal marshes of Oregon (Figure 17) are more the result of slow sea-level rise, tidal sedimentation, and gradual sediment compaction than of unrecovered coseismic

Figure 18 Changes in diatom summary water-salinity classes, which reflect changes in tidal elevations and environments, in a sediment section spanning two subduction-zone earthquake cycles near Girdwood, south-central Alaska. Corresponding RSL changes are reconstructed from diatom species data using transfer function methods. Two short periods of preseismic submergence immediately prior to the substantial coseismic subsidence marked by the contacts at the tops of peat G and peat H are highlighted on the right. Modified from Shennan I and Hamilton SL (2006) Coseismic and preseismic subsidence associated with great earthquakes in Alaska. *Quaternary Science Reviews* 25: 1–8. <http://dx.doi.org/10.1016/j.quascirev.2005.09.002>.

subsidence during great earthquakes. Along much of the coast of south-central Chile, the region of the largest earthquake of the past century (M9.5 in 1960), similar coseismically subsided soils are not widely preserved. This is probably due to largely complete postseismic recovery following many earthquakes, and to shoreline erosion and retreat during the slow fall of RSL since 6 ka (Figure 16). Recent work in Sumatra shows that subsided wetland soils may record past subduction-zone earthquakes even in tropical regions where organic material decays rapidly.

Ongoing studies of late Holocene strandlines with the most precise indicative meanings show promise for unparalleled reconstruction of strandline displacement during past earthquake cycles above subduction-zone megathrusts. Changes in the proportions of tidal microfossils (foraminifers, diatoms,

and pollen) in coastal stratigraphic sequences, first used in the 1930s to infer late Holocene sea-level changes in Europe, show decimeters to meters of coseismic subsidence during great earthquakes at the Cascadia subduction zone of western North America (Atwater and Hemphill-Haley, 1997; Hawkes et al., 2011). Similar biostratigraphic studies in wetlands above the southeastern Alaska megathrust suggest decades of preseismic subsidence just prior to as many as six past great earthquakes, perhaps due to slow slip on the megathrust just prior to great earthquakes (Figure 18). In contrast, diatom biostratigraphy in northern Japan shows about a meter of gradual coastal uplift following great earthquakes; such crustal behavior implies slow, deep, postseismic slip on the megathrust like that used to explain tide-gauge measurements in southern Chile since 1960 (Figure 19; Satake and Atwater, 2007). The

Figure 19 Stratigraphic evidence for postseismic uplift beneath a coastal marsh at Mochirippu, above the eastern Hokkaido (Japan) subduction zone. (a) Photograph and type of sediment in part of a core from the marsh; three tephra (volcanic ashes) of known age date the upper part of the core. (b) Changes in diatom summary water-salinity classes from which gradual preseismic subsidence and postseismic uplift are inferred before and after deposition of a muddy sand by a tsunami. Error bars for height estimates calculated with transfer function methods span two standard deviations. (c) Model of coseismic (sudden) uplift that converts a tide flat into a lowland forest following a great subduction-zone earthquake (Figures 13 and 15); model of gradual postseismic uplift of a tide flat inferred for Mochirippu. Modified from Sawai Y, Satake K, Kamataki T, et al. (2004) Transient uplift after a 17th-century earthquake along the Kuril subduction zone. *Science* 306: 1918–1920.

most precise studies of fossil coral microatolls, above the western Sumatran subduction zone, track complex interseismic as well as coseismic changes in apparent sea level along strike and perpendicular to the subduction zone (Figures 2, 3, 10, and 11). Briggs et al. (2006) used mostly coral-microatoll measurements supplemented with global positioning system data to construct some of the most detailed strandline maps yet compiled (0.25-m contours) of deformation above the megathrust during the M9.2 2004 and M8.7 2005 earthquakes. Corals allow uplift from the two earthquakes only 3 months apart to be measured separately (Figure 3). The high precision and short timescale of such methods is not only bridging the gap between geologic and instrumental studies of sea-level change, but in the case of coral microatolls is supplementing the modern instrumental record (Taylor et al., 2008).

Such high-resolution studies of sea-level changes throughout past earthquake cycles have considerable practical as well as theoretical value. For example, at Cascadia determining whether the coast immediately rebounded or continued to subside following the subsidence that occurred during past great earthquakes will help show which of two competing models of earthquake cycles should be used to assess earthquake hazards in the region (Wang, 2007). In the Solomon Islands, a study of coral microatolls displaced during the 2007 M8.1 earthquake showed for the first time that a single earthquake can rupture two structurally separate subducting plates (Taylor et al., 2008). This finding illustrates that the assumption that earthquakes do not rupture across major structural boundaries, which is widely used in estimating the maximum size of earthquakes in fault zones, may be invalid. Application of high-resolution methods to the study of local faults and folds in suitable coastal environments should advance our understanding of tectonic processes in non-subduction-zone settings.

Acknowledgments

This overview owes much to Lajoie's (1986) review, which has influenced many over the past quarter century. My research on Quaternary strandlines has been supported by the Earthquake Hazards Program of the U.S. Geological Survey, a USGS Gilbert Fellowship, and the U.S. Nuclear Regulatory Commission. Lee-Ann Bradley did many of the graphics. Reviews by Dan Muhs, Rob Witter, and Rich Briggs improved this overview. Muhs provided a photograph.

Introduction

The term 'forensic' may mean 'of or relating to courts of law, crime detection, or to public debate.' Therefore, 'forensic geology' (known also as 'geoforensics') may be regarded as 'the

application of geology to the investigation and detection of crime, which may come before a court of law.' Forensic geologists may assist in some types of criminal investigations to help determine if there may be an association between items and objects, which came into contact at a crime scene.

Alternatively, forensic geologists may assist in the design and implementation of a 'search' to confirm the presence or absence of objects or items buried as part of a criminal act.

Forensic geology may support crime investigations which include murder, rape, kidnapping, fraud, firearms offences, and the search for missing persons. Both 'forensics' and 'geology' have the ability to reach out to the public and to capture their imagination, and increased media coverage, TV documentaries, and film coverage has possibly benefited forensic science and geology in recent years.

The history and early developments in forensic geology may be traced back to the middle part of the 1800s and early 1900s when the collection and analysis of soils was used to determine whether there was an association between an offender, item, and/or victim of crime. This was based on the principle developed by the French medicolegal pioneer Edmund Locard, who suggested that when two objects come into contact there is always a trace left behind. Forensic geologists also contributed to criminal investigations throughout the remainder of the 1900s. For example, geologists have been working with the Federal Bureau of Investigation (FBI) since about 1935 (Murray and Tedrow, 1975).

Objectives

Forensic geology may be conveniently grouped into two categories. Firstly, 'geological evidence' (sometimes called 'trace evidence') and, secondly, 'search.' The objective of this article is to provide a general overview on 'search.' Geological evidence aspects of forensic geology are discussed elsewhere in this encyclopedia.

Forensic geology has a variety of applications, such as in policing, law enforcement, counter terrorism, domestic incidents, humanitarian, geotechnical, civil engineering, mining, minerals and material engineering, environmental pollution and contamination, hydrogeology, and fraud investigations. However, the scope of this article is limited to 'searching the ground' in a policing and law enforcement context.

Some of the information in this article is from other publications by Donnelly, Harrison, and others. Some case details and images have also been purposely changed and made anonymous to enable their publication.

Recent Developments in Forensic Geology

Since 2002, forensic geology has experienced somewhat of a global renaissance. There has been increased awareness and interest in forensic geology by the police, law enforcement, military, consultancy, academia, and the media. There have been several international meetings and conferences, and numerous text books, scientific papers, conference proceedings, and magazine/journal articles have been written (see, e.g., Bergslien, 2012; Donnelly, 2008a,b, 2009a,b, 2010, 2011; Donnelly and Harrison, 2010a,b, 2012; Harrison and Donnelly, 2008, 2009; Murray, 2004, 2005, 2011; Murray and Solebello, 2005; Murray and Tedrow, 1992; Pye and Croft, 2004; Ruffell and McKinley, 2008; Ritz et al., 2009).

A meeting was held in 2002 as part of the All-Party Parliamentary Group for Earth Science, at Westminster Palace, House of Commons, London (Donnelly, 2002a,b, 2003). This event stimulated professional and academic interests in forensic geology within the United Kingdom. Five forensic geology meetings were subsequently held at the Geological Society of London (2003, 2004, 2006, 2008, and 2010) and three at the Geological Society of America in Philadelphia (2006), Denver (2007), and Houston (2008). International Soil Forensic meetings were held in Australia (2006), Edinburgh (2007), and California (2010). The first Ibero-Americano course on forensic geology was held in Colombia (2009), with the next possibly taking place in Brazil (in 2013). Interpol held its 16th International Symposium in Lyon, France, in 2010, which was attended by forensic geologists. The GeoNZ 2010 conference in New Zealand held a session on Forensic and Evidential Geology.

In 2006, The Geological Society of London, Forensic Geoscience Group (FGG) became established to help promote and develop forensic geology. This was followed by the International Union of Geological Sciences (IUGS), Commission on Geosciences for Environmental Management (GEM) forensic geology workshops held in Uruguay (2009) and Namibia (2010). Following the success of IUGS-GEM, the IUGS Initiative on Forensic Geology (IFG) was launched during the 62nd Executive Committee Meeting of IUGS, which was held at UNESCO headquarters in Paris in 2011. The first meeting was held in Rome later in 2011 and training on search was delivered to the Australian Federal Police in Australia in 2012.

Historical Overview of Search

Traditional police methods of finding graves often involved large-scale line searches and trail-and-error excavations. These were inefficient and labor intensive, and potentially destroyed evidence or subtle ground disturbances associated with burials. These were often supported by nonspecialists such as public volunteers and local interest groups. The value of large numbers of public volunteers, or military infantry forming large lines and walking through large areas of open land or woodland, must be carefully considered.

Law enforcement officers may often be inundated with offers of assistance from a variety of specialists, each with a range of search techniques and instruments. This, combined with the absence of any recognized acceptable national or international standard, can often make search deployment decision making difficult for law enforcement officers engaged in homicide searches.

The primary assets of search volunteers are their physical mobility and ability to move over the terrain in order to use their eyes to observe the ground. As with any such groups, there is no set standard of competence as to each individual's mobility, eye sight, or knowledge to identify and interpret ground disturbances such as, for example, anomalous vegetative growth, natural ground movements, and/or animal activity. It could be concluded that such searches offer little or no value to the investigator. These types of searches may also inhibit the investigation through cross contamination of the search area, or destruction of evidence such as offender foot prints and signs of past digging, but such searches may provide the

opportunity for the offender to alibi the presence of their DNA at the crime scene by his/her participation as a 'volunteer' in the search. Despite these limitations in homicide searches, the use of large untrained groups may be the most prevalent method used. This is often driven by large numbers of the public self-deploying to the search area following awareness of the investigation or appeals made through the news media. Law enforcement personnel are then faced with highly motivated, but untrained people, wishing to assist. Images shown on broadcast media then encourage further groups to deploy and offer their services and the investigators can soon become overwhelmed. The management of this, with its associated logistical support required for large groups of searchers, becomes a full-time role. The aim can rapidly become finding more and larger areas to search in order to keep people active and motivated and demonstrating to the victim's family and local community that a large effort is being undertaken to locate the missing person. Little or no assessment is made of the geology and environment prior to the search. Critically, these types of searches can also jeopardize the investigation, as when such large areas have been 'searched' by these large untrained groups for typically 1 or 2 weeks, the investigators may be given a potentially false assurance that no evidence or burial exists. Clearly, these circumstances present challenges for law enforcement, as it would be unwise to reject any offers of assistance in an active homicide investigation with a high media and local community profile. What is important, though, is the recognition that the search actions of large untrained groups may limit or inhibit the investigation. Therefore, careful consideration should be given before allowing such groups to gain access to an area where the victim's remains are likely to be found.

Local public volunteer groups and the victim's family members may offer their services during a large-scale search. These are well-motivated individuals and some may be appropriately equipped to perform a search in their local environment. However, their training may not have been accredited by a national body and they may not necessarily be familiar with techniques to locate persons that go missing in nonsuspicious or noncriminal circumstances. They are unlikely to have any enhanced detecting technologies or equipment other than their own canine pets they have trained.

The use of specialist mountain rescue or military personnel is preferable to untrained, nonspecialist, public volunteers, or even law enforcement officers who have no formal search training. Military and mountain rescue searchers may at least provide consistent searches that conform to their own organizational standards, which can be measured and assessed even if they are not formally trained in any search techniques.

Drivers for Change

Irish republican terrorist activity in the 1970s and the bombing of the Grand Hotel in Brighton, UK, on 12 October 1984, which killed five people, resulted in an inquiry being set up. As a result of this inquiry, the UK Police established a training school, jointly with the UK military, to train specialist police officers in search techniques. These were derived from military and police search units that had received training and practice in places such as Northern Ireland and the Middle East. Each

police force or geographic region within the United Kingdom has officers who receive nationally delivered training, focused on counterterrorist search techniques. This includes finding terrorist resources or hidden improvised explosive devices and other burials (such as graves).

Search

Law enforcement activities may be divided into one of four primary functions: investigation, interview, search, and recovery. Of these, the 'search' function appears to be the least developed and advanced. A search is 'the application and management of systematic procedures and appropriate detection equipment to locate specific targets' (Harrison et al., 2006). It may be regarded as 'the skill of looking and the art of finding.' An 'Offensive/Detective Search' is undertaken when evidence is required after a crime has occurred. The objective of this type of search would be to restrict a suspect or offender's ability to carry out criminal activities, obtain evidence or intelligence, or locate a buried or concealed object/item. For example, an offensive search may be conducted to locate firearms. A 'Protective/Defensive Search' is preventative and proactive and is carried out to confirm the absence of a specified item, object, or person within an area or location and allow freedom of movement and access to the general public. For example, a protective search may be undertaken to ensure that there are no buried explosive devices ahead of a VIP visit to a particular venue (Harrison et al., 2006; Harrison and Donnelly, 2009). Some of the objectives of a search are summarized in Table 1.

A police/law enforcement search may include the searches of people/individuals, missing persons, mass fatalities, crime scenes, roads and highways, railways, buildings and engineered structures, vehicles, and ground and water bodies (e.g., sea, lake, ponds, reservoirs, canals, streams, rivers) (Ruffell, 2007).

Table 1 Some principal objectives of search

<i>Search objective</i>	<i>Details</i>
Locate buried or concealed objects/items	Objects buried in the ground may include unmarked homicide or mass graves, explosives, money, firearms, drugs, jewelry, etc. (known as 'the target')
Locate missing persons	Law enforcement searches are conducted for voluntarily and suspicious missing persons
Deprive criminals of resources and opportunities	Items/objects required by criminals (e.g., firearms) may be searched for, to reduce the ability of the criminals to commit offences
Protect vulnerable targets	A search may be conducted to protect and safeguard a person, group of people, or the event itself
Intelligence gathering	A search may obtain information of use in crime prevention
Evidence gathering	A search may obtain information of use in supporting a prosecution

Ground Searches

The responsibility of a ground search may rest with a Senior Investigative Officer (known as an SIO in the United Kingdom). Usually, the search may be designed, managed, and supervised by a Police Search Advisor (POLSA in the United Kingdom) and a trained Police Search Team (PST). The SIO/POLSA may decide what other specialists and resources may be required to help locate the target buried in the ground.

Geologists may explore and investigate the ground to locate mineral resources, investigate geological hazards, or determine the ground characteristics ahead of civil engineering construction. Many of these exploratory and investigative methods, techniques, and instruments used are applicable to law enforcement ground searches. Geological exploration and ground investigations usually take place in a phased approach, starting with a desk study involving the collation, review, and analysis of preexisting data and information. This may be followed by a reconnaissance site visit (known also as a walk-over survey) to make observations on the geology, geomorphology, and ground conditions, and to determine any logistical, technical, and environmental constraints that may be relevant for any future detailed ground investigations and/or monitoring. This philosophy has been successfully applied to law enforcement searches in recent years (Donnelly, 2010; Donnelly and Harrison, 2010a).

Geological advice on search can be variable, depending on the specific nature of each operational case. This advice may be limited to the provision of information over the telephone, or the design, implementation, and management of a search. The duration of a search may also vary, lasting from hours to days and, in high profile and rarer cases, weeks to months (rarely years). During the design stages of a search, it will be desirable to strike a pragmatic balance between cost and resources. This, however, will be influenced by the nature of the target being sought and the profile of the individual case.

Searches for burials may be grouped into one of five categories, as summarized in Table 2 (Harrison and Donnelly, 2009).

Before the implementation of a ground search for a homicide grave, it will be helpful to gain a basic understanding of the behavioral characteristics associated with the disposal of human remains in an unmarked grave. Often, this may be provided from a clinical psychologist, environmental profiler, or highly trained police search advisor. These are summarized in Table 3.

Conceptual Geological Model

Burials in the ground usually take place in soils or weak or weathered rock. Therefore, it is necessary to understand the geology of ground at and in the immediate vicinity of the burial place. One of the most valuable roles a forensic geologist can provide the police/law enforcement officer is a geological model of the search area and target. For example, in the past a law enforcement officer may have chosen a particular type of instrument because it worked successfully in another part of the country where the geology and ground conditions may

Table 2 Search philosophy

Standard operating procedure (SOP)	A written document is applied to a search to provide a search strategy, instrument types and search assets deployed, assurance of consistency throughout the search, opportunities for critical and peer review, and an official record of the search
Intelligence-led	Searches should not be undertaken speculatively but must be intelligence-led and based on hypotheses. Geological, geochemical, or geophysical techniques must be based on sound scientific justification
Feature-focused	Features of the landscape/ground may be consciously or subconsciously used by offenders to bury objects in the ground (known sometimes as the Winthrop technique). The location may be familiar to the offender and this could facilitate the choice of the grave/excavation location. If the offender's mode of operation can be determined by the investigators, this may significantly reduce the search area
Scenario-based searching	Searches are conducted using intelligence and information from behavioral profiling and/or an assessment of the victims (known also as a victimology assessment). This often may require contributions from other forensic specialists such as a clinical psychologist or an environmental profiler. A hypothesis will be generated by profiling the offender and/or victim to identify possible locations where a burial may have taken place. Comparison with data for other similar crimes may be used to facilitate this process along with factors such as likely distance traveled and suitability of locations for burial. This method provides a more objective approach and removes the subjective 'instinctive,' 'gut-feeling,' or 'hunch' used as a search basis in some historical searches. A range of scenarios may be generated, which can then be considered and prioritized in a proportionate manner
Search and Rescue	Search and Rescue is applied to lost or injured, missing persons, or groups of people who wish to be found (i.e., they are actively trying to be recovered or self-discovered). Estimations are made to identify a search area to provide a search radius from the last known place the person was seen, or where evidence was found to verify that person had been. Since this is based on assumptions and subjective calculations, this may introduce a degree of vulnerability into this particular approach. A hypothesis may be generated based on a correlation between the person's mobility, distance, and time. Where significant time has passed, the search areas may be large and subdivided into search zones, including several search teams, but coordinated by a search manager

Table 3 Attributes of victim homicide disposal in a shallow grave

Attribute	Characteristics
Diggability and principal of least effort	Minimizing the time spent digging and reinstating a grave may be significant for the offender. The offender may choose a location that offers the opportunity to quickly dig an excavation of length, width, and depth for the victim to be concealed. For example, softer soils such as peat and sand may offer better alternatives than clay- and gravel-rich soils
Bulking, excess soil, and scarring	Digging shallow graves may result in an excess of soil caused by bulking (the expansion of the soil following its <i>in situ</i> removal) and the volume taken up by the deceased. Digging and excess soil may produce scarring of the ground but this may become less apparent with time due to weathering and erosion, or vegetation growth
Concealment	The location of the grave may have a low witness potential and is likely to be out of view from the public or passers-by to enable the covert burial to take place
Familiar location	'We go where we know' and therefore the location of a grave may be familiar to the offender. If the offender is seen or compromised, he may have an explanation for his presence at that particular location. Familiar locations will also facilitate navigation (particularly if at night) and escape routes. This will usually be aided by the recognition of physical features of the landscape

have been different, or because it happened to be available at the time the search was being conducted.

Mineral exploration geologists, engineering geologists, and geomorphologists are trained to 'read the ground.' They usually have the luxury of some 'time' to develop a more detailed understanding of the ground conditions ahead of the development of a mine, the building of an engineered structure, or the prediction of risks associated with a geological hazard. This may be facilitated by the acquisition of geological maps, memoirs, reports, and papers, supplemented by, for example, geological mapping, analysis of aerial photographs and satellite images, drilling, trenching, and geophysical and geochemical surveys.

Law enforcement investigations, particularly those involving the search for missing or vulnerable persons, or unmarked homicide graves, may be 'time critical' and therefore the forensic geologist may be required to quickly develop a conceptual geological model (CGM) for the target. This will often be based on the intelligence provided by the police/law enforcement officers on the possible burial site(s).

A CGM provides an estimate of what is likely to be found and the possible conditions of the target (Figure 1). This is a 'model', and as such it must be challenged and tested as more information becomes available. This may be gained from the progressive acquisition of additional geological data/observations from the reconnaissance (walk-over) survey and the main search itself, and then the model can be updated.

As a result of the variability and complexity of the ground, the geological model is unique to each particular crime scene or search area. The more detailed and reliable the original geological information and police intelligence, the more accurate will be the CGM for the search area. Those based on high-quality intelligence and good-quality published geological maps will be the most reliable. However, even where high-quality geological maps have been published, there is still the need to conduct detailed site reconnaissance walk-over surveys to provide the necessary geological observations that will be specific to the individual search area. For instance, published geological maps and memoirs may not necessarily provide information on the detailed stratigraphy, principal lithological (rock) types, groundwater seeps and springs, and areas of ground disturbances (e.g., scarring, scarps, fissures, compression, debris accumulations, changes in slope profile, topography, geomorphology, and landslides and mass wasting, including falls, topples, slides, and slips).

The development of a geological model will be based on the training and experiences of the individual geologist, case-specific intelligence, and the time and resources available. The accuracy of the model will improve as more information is made available and as the search advances. The model will be verified only when the target has been located and recovered.

The strength of a CGM in a police/law enforcement search for a burial is in the provision of the following:

- Determination of the 'detectables' (i.e., what can potentially be found). For example, although human remains may be the desired target, it may be relevant to design a search to locate the 'indicator' or 'associated' target objects such as any clothing, coinage, or jewelry. (This is the adaptation of a typical strategy deployed in mineral exploration, for instance, where some metallic ore minerals, diamonds, or other gemstones are being explored for; the exploration strategy may be designed to locate the minerals associated with the desired mineral.)
- Estimation of the age, geometry, size, depth, and expected duration of preservation.
- Information on the geology in the immediate vicinity of the burial: for example, the physical, chemical, and geotechnical characteristics of the soils, rocks, and 'made ground,' depth to bedrock, degree and intensity of weathering, groundwater, past mining and mineralization (metaliferous minerals in the ground may negate the deployment of certain geophysical search assets).
- Knowledge of the number of interactive, dynamic, geological, and geomorphological processes that may have taken place before, during, and since burial took place. These may have influenced the target and associated detectables. These natural processes are variable and occur over a wide variety of time frames, from days to millennia. They include, for instance, wind, stream and river erosion, landslide, mass wasting, and weathering. The forensic geologists will determine which (if any) of these processes may be significant in affecting the grave's location. The processes may have also been influenced by the activities of the offender, such as digging and soil reinstatement. For example, some peat deposits in parts of the United Kingdom may promote the

Figure 1 Conceptual geological model (CGM) for a shallow homicide grave (after Donnelly, 2002a, 2008a, in Donnelly, 2010; Harrison and Donnelly, 2008, 2009).

preservation of human tissue, whereas others, such as granular (sand) soils, may promote decomposition. Determination of the hydrogeology and the location of hydrogeological domains (cells) and groundwater flow paths may influence the generation of leachate and any volatile organic compounds (VOCs; known also as gas/scent/odor), which may be relevant for canine searches (Figure 2).

- Predetermination of the most suitable search assets to be used that would provide the greatest opportunity to locate the desired target/burial.
- Identification of the optimum search strategy and methodology for the deployment of search assets and instrumentation.

Therefore, the development of a CGM provides an estimation of the ground conditions and facilitates the optimum choice of search assets most likely to locate the target.

Search Planning and Phases

Ground searches may be divided into three phases:

Presearch Phase

The presearch phase will involve the initial briefing between the forensic geologist and police/law enforcement officers. They will discuss the type/nature of the target desired to be found and determine precisely what expertise the geologist may be able to offer the search team. Terms of reference, deliverables, and contractual agreements may be discussed at this stage. Police intelligence and geological data will be collated, reviewed, and analyzed. This will form the precursory stages of a reconnaissance walk-over survey of the crime scene/search area. The forensic geologist will develop a CGM at this stage, including soil types and thicknesses, principal rock types, hydrogeology, and geomorphological processes active before, during, and after the burial took place. Operational and logistical constraints may also be observed during the initial walk-over survey. For example, the presence of utilities, overhead power lines, or metal fences may inhibit or exclude the deployment of certain types of geophysical techniques. It is also at this stage of the search that operational matters will be considered, such as the management of the public, media, psychics, and family and friends of the victim. Any ground disturbances observed, such as subsidence, settlement, and scarring, can be

Figure 2 Schematic model to show the generation of a leachate plume and gas/scent/odor and how this may be potentially controlled by the geology and increase the search target area (after Donnelly, 2002a, in Donnelly, 2010; Harrison and Donnelly, 2008, 2009).

assessed at this stage to determine whether these were generated by geomorphological processes, animal burrowing activity, the activities of man (e.g., mining, farming), or potentially associated with the action of the offender (Figure 3).

The determination of ground diggability and production of color-coded RAG (red–amber–green) maps may also be developed during the initial reconnaissance survey to prioritize the search area. Geological mapping and the determination of soil types and depths by probing or the digging of exploratory trial pits may be required at this stage to determine the offender's relative ease or difficulty in digging a shallow excavation for disposal of any human remains or associated objects. In a police/military search, areas shown as 'red' are usually of the highest priority (Donnelly and Harrison, 2010a). The CGM and diggability map will predetermine the most appropriate types of search assets required to deliver a high-assurance search.

The search area should be identified during the presearch stage and, if required, protected by a police cordon. The limits of the search area may vary considerably, from the confines of a small garden at the back of a house to an entire mountain side. Other typical search areas include, for example, parks and other public open spaces in towns and cities, coastlines, forest/woodland areas, caves, abandoned mines and quarries, landfill and other areas of waste disposal/tipping, agricultural land, railway corridors, tracks, and roadside verges.

Presearch reconnaissance visits to the search area/crime scene may also benefit from the presence of the investigative officers or other specialists, such as a forensic botanist, palynologist, or environmental profiler. This may allow hypothesis generation from the recognition of any primary, secondary, or

Figure 3 Settlement of the ground and changes in soil color that may potentially be observed during the initial reconnaissance walk-over inspection (Donnelly and Harrison, 2010b, photograph by Harrison).

tertiary 'Winthrop Markers,' which may have potentially formed part of the offender's mode of operation.

The objective and deliverable of the presearch phase will be the production of a standard operational procedure (SOP) to provide assurance and consistency throughout the search.

Search Phase

The aim of the main search phase is to implement the SOP to provide a high-level assurance search to verify the presence of, or confirm the absence of, the desired target. The search may begin with a briefing to the police search team and associated support personnel. This will provide information on the aims and objectives of the search, nature of the target objects to be found, search asset, strategy, methodology, agreed methods for the recovery, identification and recording of any finds, and the search management and reporting structure. Any operational, logistical, and health and safety matters will also be provided at this stage. All search personnel must be already familiarized with the use of the search assets and instruments, and be appropriately qualified, trained, and experienced (Figure 4).

The forensic geologists will be responsible to assist with the design and implementation of the search to locate the target. This will also require effective communications between the forensic geologist, police/law enforcement officers, and other specialists (Donnelly, 2008a). If possible, searches must initially be noninvasive to minimize any cross contamination and ground disturbances. However, a degree of digging and trial pit excavation or probing will inevitably be required to verify the presence of a target or to investigate any positive anomaly provided by the geophysical instruments or specialist canine. All surface and buried finds will require formal identification, recording, and recovery usually by nongeological specialists. This may include, for example, a forensic anthropologist, archaeologist, crime scene investigator, and/or exhibits officer.

Postsearch Phase

Upon completion of a search, the search area and any finds must be mapped and accurately recorded. The nature of this documentation will be variable and case-specific, but may include photographic records, a descriptive search account, any deviations from the SOP, conventional geological/geomorphological mapping, the geology in the vicinity of any finds, an account of the soil types and depths, the degree and intensity of weathering, groundwater presence, and dimensions and conditions of any finds. The presence of soils and rock fragments from another unknown location associated with the body or target object may require sampling and analysis by a forensic geologist suitably trained and experienced in geological (trace) evidence (Lee et al., 2009).

Surveying, including basic geological and topographic mapping, the deployment of precise leveling, global positioning systems (GPS), total station theodolite, or laser scanning techniques, may be required, and in some forces specialist forensic and surveying units may be deployed to fill this role.

A search debriefing forms an important part of the overall search procedure. This provides the opportunity for each search team member and the investigative team to offer views and opinions on the search strategy, methodology, and assets used. Where possible, any feedback provided and 'lessons learned' should be recorded and if necessary fed into future similar searches and the SOP.

All searches must have a predetermined 'exit strategy' to carefully manage the outcome of the search.

Search Assets

Search assets are techniques, instruments, and methods that may be used by a forensic geologist to help search the ground to locate the desired target. In general, ground searches proceed

Figure 4 Defining the search area and setting up search lanes during the initial stages of a search (Donnelly and Harrison, 2010b, photograph by Donnelly).

from the macrolevel to the microlevel and from the noninvasive to the invasive. Based on this, some of the principal search assets may be grouped into the following categories:

- *Remote sensing* (also known as *Earth observation*). These methods acquire data about the ground without direct contact, obtained from the air (fixed-wing aircraft, helicopter, or a drone) or satellites. Advances in remote sensing technology and improved resolution mean that some of these techniques can be increasingly applied for the investigation of individual crime scenes and search areas. The acquisition and analysis of pre- and postburial conventional aerial photography (vertical and oblique), when used in association with geological mapping, offers a particularly useful technique to help locate graves or to assist with the planning and management of a search strategy. Other remote sensing methods include, for example, infrared photography, photogrammetry, elevation modeling, hyperspectral and multispectral imaging, laser scanning, long-distance light detection and ranging (LiDAR), synthetic aperture radar (SAR) and interferometry, and X-ray imagery. Large or complex search data may be managed and analyzed using geographic information systems (GIS) and geostatistics. Examples of successful applications of remote sensing in forensic geology can be found in [Ruffell and McKinley \(2008\)](#).
- *Geological and geomorphological mapping*. As noted earlier, geological mapping forms an important part of the initial site reconnaissance walk-over survey. Detailed geological maps for crime scenes and search areas may potentially identify higher priority search areas, provide an estimate of diggability, and identify subtle ground disturbances associated with digging and burials ([Donnelly and Harrison, 2010a](#)).
- *Geological analysis of intelligence*. Interview statements, crime scene photographs, body disposal plans, letters from offenders, and other types of intelligence may sometimes be of benefit when reviewed and analyzed from a geological perspective. This could provide information to assist with a search. This may be particularly valuable if geological landmarks or rock exposures occur in the background of photographs, or geomorphological features (e.g., waterfalls, steep slopes, streams, sandstone banks, shale gullies) are mentioned in documents. A good example of this followed the terrorist attack on the World Trade Centre, in New York, on September 11, 2001, when a videotape showed Osama Bin Laden and limestone rocks which cropped out in the background. These were recognized by a geologist who had field experience in Afghanistan where these rocks occurred in a specific region ([Pinsker, 2002](#)).
- *Probing* (known also as *auguring* or *window sampling*). This may sometimes be regarded as an 'old fashioned' search technique. For example, this method was used in the 1960s during a search of Saddleworth Moor, UK, for missing children (later to become infamously known as 'The Moors Murders'), whereby lines of public volunteers would 'line search' and stick a wooden probe into the ground to smell for any decomposition possibly associated with decomposing human remains. However, soil probes have advanced significantly, and there are now a variety of soil probes designed to suit organic (peat), granular (sand), or cohesive (clay) soil or weathered rock conditions, or combinations thereof. A line of highly trained and well-disciplined police officers, probing on a grid of at least 0.2 m, can provide an effective, although time-consuming, method to search for buried objects or recover samples of the target. Probing techniques rely on the ability to detect resistance caused by the target. Probing may also be undertaken to facilitate canine searches, if the probe holes are allowed to vent for a short period ahead of the deployment of cadaver dogs (this is best undertaken in favorable barometric pressure conditions). Before probing takes place, control measures should be established so the search teams can practice this technique on buried items comparable to the target ([Figure 5; Ruffell, 2004](#)).
- *Trenching*. Trenching of the ground takes place by the use of handheld digging implements including spades, picks, and mattocks. Exploratory 'trial pits' or 'inspection pits' may be dug to act on intelligence considered to be reliable or to verify a geophysical anomaly or positive canine indication.
- *Geophysics*. A variety of geophysical surveying techniques are available that may potentially be used to assist with ground searches. However, each method should be deployed only following the careful investigation and characterization of the geology at and in the immediate vicinity of the crime scene/search area. An advantage of geophysical surveys is their ability to be deployed noninvasively (without contact with the ground). This reduces the possibility of any evidential contamination and damage to crime scenes. Common geophysical techniques that may potentially be used to search the ground include ground penetrating radar (GPR), conventional metal detectors, as well as electromagnetic (conductivity), resistivity, and magnetic probes. Less common methods are seismic and microgravity. When required, some geophysical surveys may be deployed remotely on board a fixed-wing aircraft or helicopter. Alternatively, they may be towed behind a 4×4 vehicle or tractor when large tracts of relatively flat land are required to be investigated. The results of geophysical investigations are measurements showing vertical and lateral variation of the physical properties of the ground, often displayed in plan or as a series of cross and longitudinal sections. These must be analyzed and interpreted in association with a detailed understanding of the search area's specific geology and intelligence ([Figure 6](#)). Positive geophysical anomalies will require subsequent investigation by excavation ([Figure 7; Fenning and Donnelly, 2004; Ruffell, 2005](#)).
- *Hydrochemistry and geochemistry*. Objects buried in the ground may be subjected to geological processes of weathering and erosion. For example, the decomposition of human remains in unmarked graves may be influenced by groundwater flows. This may lead to the generation of a 'leachate' plume, which could flow from the grave through the soils and rocks. The generation, geometry, and distance traveled by this plume will be dependent on several inter-related factors including the porosity and permeability of the soils and rocks, geological structure, and local weather conditions. In these circumstances, VOCs (known also as

Figure 5 Different line probing techniques: one method using a line of trained and disciplined police officers and a forensic geologist (left), the other method requiring the deployment of two police officers to search a small area of ground in Eastern Europe (after Donnelly, 2008b; Donnelly and Harrison, 2010b, photographs by Donnelly).

Figure 6 A noninvasive geophysical survey being conducted to search part of a coastline for a missing person (Donnelly and Harrison, 2010b, photograph by Harrison).

gas/scent/odor) may also be generated. The collection and analysis of soil and/or groundwater samples may provide the opportunity for leachate and VOC detection (Figure 8). The isotopic analysis of teeth and bone, using strontium-87 and carbon-13, may also have some application in search or help determine geographical provenance of the deceased. By comparison with better established geophysical methods, geochemistry and hydrochemistry appear to be less well developed in terms of their applications to search,

but nevertheless these may be worthy of consideration in certain circumstances.

- *Cadaver dogs (victim recovery dogs)*. Although the use of highly trained specialist police dogs is not conventionally a geological search technique, their deployment with a highly trained and experienced dog handler and geological search advisor may provide an important search option. The positive reaction of a dog may be influenced by the geological and environmental conditions, and the better

the understanding of these controlling measures, the greater will be the likelihood for the dogs to be deployed to high levels of assurance (Figure 9).

Soils and Sediment

R C Murray, University of Montana, Missoula, MT, USA

History

As with so many other kinds of physical evidence, forensic examination of soils and sediment, forensic geology, began with the writings of Sir Arthur Conan Doyle, who wrote the Sherlock Holmes series between 1887 and 1927. He was a physician who apparently had two motives: writing saleable literature and using his scientific expertise to encourage the use of scientific methods and scientific thinking as evidence. Holmes could tell where someone had walked around London from the splotches of dirt on their pants.

Gross (1893), an Austrian forensic scientist, wrote the book *Handbook for Examining Magistrates*, in which he suggested that: “perhaps the dirt on someone’s shoes could tell more about where a person had last been than toilsome inquiries.” It was only a matter of time before these ideas from an author of fiction and criminalists’ handbook would appear in a courtroom. In 1908, German chemist Georg Popp undertook the study of soil evidence in the homicide case of Margarethe Filbert. In this case, Popp was able to demonstrate that soil samples from two locations associated with the crime had similar characteristics to those collected from the suspects’ shoes. In addition to using soil from the suspects’ shoes, he was able to show a sequence of events in soil accumulation that was consistent with the theory of the crime; he found no soil evidence that supported the suspect’s alibi.

A century later, the use of geologic materials in criminal and civil cases is commonplace. Many state and private laboratories around the world have trace evidence examiners qualified to examine soil, glass, and related material. See Murray (2004), Pye (2007), and Ruffell and McKinley (2008) for more detail.

Soil and Related Material as Evidence

The value of any type of physical evidence in large part depends on how many different kinds of a given material can be characterized, how many kinds exist on Earth, and how they are distributed. The value of soil evidence rests on the fact that there are an almost unlimited number of rock types, mineral types, and fossils, as well as durable man-made materials such as glass and brick and concrete. In addition, it is not uncommon for soil material to have incorporated man-made particles such as plastics and metals, and chemicals such as fertilizers and pesticides. Each of these constituents can be identified in soils, and are useful to pin down the source of the sample.

Forensic geology studies vary in scope. A common type of investigation involves identifying a material that is key to a case – for example, examining pigments in an oil painting or material in a sculpture when authenticity or value is at issue. Identification is also important in questions of mining, mineral, or gem fraud, to determine if the material is what its sellers claim it to be. The presence of fire-resistant safe

insulation on a person or their property may provide probable cause for further investigation of burglary.

Beyond identification, forensic geologists can also look at the source of particular material. Here the examiner needs a broad knowledge of the geology and the best geologic and soil maps to answer questions. For example, if the soil on a body does not match the location where the body is found, from where was the body moved? Such studies are often called ‘an aid to an investigation.’ Similarly, examiners can compare two samples, one associated with the suspect and the other collected from the crime scene, to see if they had a common source: Does the soil on the suspect’s shoe have similar characteristics to the soil type collected at the crime scene (Junger, 1996)? Forensic geologists are also involved in the search for bodies and other objects buried in soil. More details on the subject are available elsewhere in the encyclopedia.

Another new developing area of forensic geology is its use in intelligence work. A person, for example, may claim to have never been to a particular location, but is then found with rocks from that spot, thus linking the individual to a geographic location. Remember the outcrop behind Osama bin Laden on TV after September 11? What was the location? A geologist who has done field work in the area would be able to locate that outcrop, and that actually happened: geologist John Shroder was able to identify the region where bin Laden had been sighted in Afghanistan in 2001. As with all class evidence, geologic evidence rarely provides a unique solution for which the legal mind cannot imagine another explanation. However, the evidence may be important in establishing guilt or innocence. There are some exceptions, as illustrated by the following three cases.

Murder and the Pond

The murder of John Bruce Dodson produced one of the most interesting cases in the entire history of forensic geology. Here, the geologic evidence is unequivocal in that it tied the suspect directly to the crime and eliminated the suspect’s alibi. Most importantly, the investigator of the crime recognized the potential importance of the geologic evidence and arranged for the examination of that evidence. The testimony of the forensic geologist was critical to the prosecution of the case. The case began on 15 October 1995, when John Dodson was found dead while on a hunting trip with his wife of 3 months, Janice. The scene was high in the Uncompahgre Mountains of western Colorado. At first glance, it appeared to be a hunting accident. However, the autopsy revealed two bullet wounds to the body and one bullet hole through John’s orange vest.

The investigation showed that the Dodsons were camped near other hunters, one of whom was a Texas law enforcement officer. He responded to Janice’s frantic call that her husband had been shot. She was standing about 200 yards from the

camp in a grassy field along a fence line. The officer determined that John was dead and started the process of getting help. Prior to calling for help, Janice had returned to her camp and removed her hunting coveralls, which were covered with mud from the knees down. She later told investigators that she had stepped into a mud bog along the fence near camp. Investigators found a 0.308-caliber shell case approximately 60 yards from the body. In addition, they found a 0.308-caliber bullet in the ground on the other side of the fence, which created a direct line from the location of the case to the body to the bullet.

Janice's ex-husband, J.C. Lee, was also camped three quarters of a mile from the Dodsons. Janice knew the site was his favorite camp location. He naturally came under suspicion. However, Lee was hunting far away from camp with his boss at the time of the shooting. Most importantly, Lee reported to investigators that while he was out hunting, someone had stolen his 0.308 rifle and a box of 0.308 cartridges from his tent. Winter comes early at 9000 ft in the Uncompahgre, and little more could be done at the scene. However, investigators Bill Booth, Dave Martinez, and Wayne Bryant returned during the summers of 1996, 1997, and 1998 and searched for the rifle and other evidence. They tried to search every place a weapon could have been hidden. They combed the entire area, including ponds, with metal detectors in hope of finding the rifle; it has never been found. During the final search of the pond near Janice's ex-husband's camp, Al Bieber of Necro-Search International commented that the mud in and around a cattle pond near Lee's camp was bentonite, a clay that someone brought to the pond to stop the water from seeping out of the bottom. That evening, Booth and Martinez were camped near the crime scene. They were discussing the evidence in the case when investigator Booth said, "The mud." He was referring to the dried mud that was found on Janice Dodson's clothing. If Janice had obtained the rifle from Lee's camp, she would most likely have stepped or fallen into the bentonite clay that drained across the road from the cattle pond (Figure 1). Remembering Janice's statement that she was returning to camp on the morning of the crime and stepped into a mud bog near her camp, Booth and Martinez decided

Figure 1 Pond lined with bentonite clay where Janice Dodson got clay on her shoes and pants when she went to steal the rifle that she used to kill her husband John.

they needed to obtain dried mud samples from the bog near the Dodsons' camp, the area around a pond nearby the camp, and the human-made pond and runoff near Lee's camp.

Booth and Martinez packaged the dried mud from each location and sent the samples along with the dried mud that had been recovered from Janice's coveralls to the laboratory section of the Colorado Bureau of Investigation in Denver, where it was examined by Jacqueline Battles, a forensic scientist and lab agent. She concluded and later testified to the fact that the dried mud found on Janice Dodson's clothing was consistent with the dried mud recovered from the pond near Lee's camp. The dried mud that had been recovered from Janice's overalls was found not to be consistent with the mud bog or the pond near her camp. This was a breaking point in the case that allowed Booth and Martinez to put Janice Dodson in her ex-husband's camp around the time his rifle had been stolen. There are no other bentonite-lined ponds in the area and no bentonite deposits.

Booth and Martinez went to Texas and served an arrest warrant on Janice. She was extradited to Colorado, tried in court, and convicted in the murder of John Bruce Dodson. The jury understood the results that followed Booth's insightful 'mud' exclamation. Janice is now serving a life sentence without the possibility of parole in Colorado's state prison for women. An appreciation of the value of soil evidence and the collection of that evidence was critical in this case.

Oil Slicks and Sands

A case that illustrates many of the issues involved in comparing soil and related material occurred in Canada a few years ago. The body of 8-year-old Gupta Rajesh was found alongside a road outside of Scarborough, Ontario. The back of his shirt had a smear of oily material, and the preliminary conclusion was that he was the victim of a hit and run accident, with the oily material coming from the undercarriage of a vehicle. However, forensic geologist William Graves of the Centre of Forensic Sciences in Toronto examined the oily material and the particles suspended in it; the results told a different story.

Investigators had collected samples of oily material on the floor of an indoor concrete parking garage where a suspect, Sarbjit Minhas, parked her automobile. Analysis of the samples showed that the sand and other particles within the oil from the victim's clothes and the parking garage were similar. Analysis of the oil from the victim's shirt and garage floor showed them both to be similar. It is also important that they were different from oil collected on the floor of ten other garages in the area.

Particles in samples from the victim's clothes and the suspect's parking place provided considerable information. The sand from both samples was sieved, and subsamples produced of the various size grades for the two samples. When compared after the oil had been removed, the color of each pair of subsamples was identical. Additionally, the heavy minerals in both samples were similar, and three distinct kinds of glass were found in the two samples: amber glass, tempered glass, and light bulb glass. Each of the different glasses was identical in refractive index value (the amount a ray of light bends when passing through the glass into another medium). Small particles of yellow paint with attached glass beads were

found in both samples. This type of paint is often found on center stripes of highways and reflects light.

Graves concluded that there was a high probability that the body of Gupta Rajesh had been in contact with the concrete floor of the garage at the place where the suspect parked her car. During that contact there had been a transfer of oil and its contained particles to the back of his shirt. Minhas was tried in the Superior Court of the Province of Ontario in November 1983 and convicted, with help from testimony by Graves.

All Soil Quarries Are Different

A classic aid to an investigation case occurred in southern Australia a few years ago. Neighbors heard a struggle taking place at the home of two women. When police arrived, the women and their car were missing. The car broke down over 100 miles away. When the car was found, the suspect had returned to the car with a mechanic. The trunk of the car contained a shovel with soil attached. There was also a lot of blood. Rob Fitzpatrick, Director of the Centre for Australian Forensic Soil Science, examined the soil and the shovel. The soil on the back of the shovel had been smeared, indicating the shovel had been used to pat down moist soil. Based on his knowledge of the local soils, Fitzpatrick determined that the soil on the shovel came from one of the local residual soil gravel quarries. The minerals on the shovel soil narrowed the search down to a small group of quarries. Samples from these quarries were collected and one produced identical minerals to the soil on the shovel. Rain had obliterated any sign of digging or footprints in that quarry. Police staked out that quarry, and within 3 days a fox arrived, started digging and unearthed the bodies. This led to the arrest and conviction of the man who came back to get the disabled car (Fitzpatrick et al., 2007).

Examination Methods

There are various instruments, methods, and procedures that are used to study minerals, rocks, soils, and related materials for forensic purposes (Murray, 2004). These methods are used to collect data from the various questioned and known samples that are then used to make the judgment of comparison or lack of comparison. All are methods that have long been shown to be reliable in obtaining information about soils. The evidential value of some of these methods is greater than others. Because of the extreme diversity of soils and related material, the examiner may decide that in a particular case some other method will provide information that will assist in reaching a conclusion. Because soils often have added particles such as fibers, hair, and/or paint chips these can be collected for examination by experts in those forensic science fields. One of the reasons microscopic examination is so important is that it is only way that particles of other forms of evidence can be found and unusual mineral particles discovered. We must remember that examination is focused on determining whether two samples have the same properties and thus have the possibility of having a common source. That determination is greatly strengthened when rare and unusual minerals and particles are found. The experienced forensic geologist can express an opinion based on experience and education. The strength of that opinion is often based on

knowledge of the rarity of particular minerals, rocks, particles, and related properties.

Color

Color is one of the most important identifying characteristics of minerals and soils. Minerals form a mosaic of grays, yellows, browns, reds, blacks, and even greens and brilliant purples. Virtually all possible colors of the visible light spectrum are represented. With most geologic materials and soils, the native minerals contribute directly to the soil color. However, the soil-forming processes generally produce coatings and staining on the grains that result in changes in color.

In the 1970s, investigators at the Home Office Forensic Science Service in Great Britain studied the use of color as an examination method and made many contributions to establishing the study of color as an important first step (Dudley, 1975). Sugita and Marumo (1996) of the National Research Institute of Police Science in Tokyo studied the use of color and provided important ideas that firmly established color as an important, useful method in screening samples. It is important first to record the color of the untreated soil sample and then remove the organic particles so that the true color and appearance of the sand grains can be studied.

In studying soil samples for forensic purposes, the sample is normally dried at approximately 100 °C and viewed with natural light (Figure 2). A north-facing window is a good location for such observations. Such studies should be made on samples that have the same general size distribution of particles. The color of samples prepared from the individual sieved-out particle size ranges gives important additional data.

Instrumental determination of color provides more quantitative information and can now be done with a precision that exceeds the human eye. Pye (2007) found that rapid, reliable, and highly reproducible results are achieved using the Minolta™ CM-2002 Photospectrometer. Calibration of the instrument is carried out for every analysis to black, white, and CERAM II color standard materials. Guedes et al. (2009) provided a study of the application of instrumental methods for forensic application.

Figure 2 Two soil samples available for examination for color comparison.

Particle Size Distribution

The determination of the distribution of particle sizes in a sample can often provide significant evidence. This determination may be done for a variety of reasons (1) to produce samples for comparison studies that are similar, in which case, the control sample may contain some larger or smaller particles that are not present in the questioned or associated sample and they must be removed; (2) the samples may be broken down into subsamples in which all the particles are in the same size range for mineral or color studies; (3) a determination of the distribution of sizes of particles may be produced as a method of comparison. A diagram showing the distribution of grain sizes can be used as a presentation and in many cases may be of evidential value.

The basic methods used for the separation of sizes are (1) passing the sample through a nest of wire sieves, with the size of the openings decreasing from top to bottom (Figure 3), (2) determining the rate of settling of the grains in a fluid, which is a measure of the size of the particles, and (3) using instruments that measure the size of particles in a microscopic view and record the number of particles of each size. The distribution of particle sizes is then plotted on a diagram.

Figure 3 Nest of sieves used to separate particles into different size grades and a diagram showing the size distribution of particles.

When a transfer is made from a soil it is unlikely that the transferred sample is truly representative of the distribution of sizes that existed at that place. For this reason, two samples that are to be compared using grain size distribution may not show exactly the same distribution of grain sizes. The method can be useful in coming to the conclusion of comparison or lack of comparison, but is seldom definitive in itself.

Stereo Binocular Microscope

The stereo binocular microscope can be a most useful tool to the forensic geologist. After an analysis of color has been made, the information that can be obtained by examination of soil samples with this instrument makes it the logical first step in the direct examination of particles (Figure 4).

Some of these microscopes are seated on a base that contains a second light source so that objects can be viewed in both transmitted and reflected light. When the transmitted light is polarized the microscope may be used for both stereo reflected light viewing and low-power transmitted polarizing light studies. Objects as small as $\sim 10 \mu\text{m}$ in diameter can be viewed with the stereo binocular microscope.

In examining a soil sample or similar material, the scientist will commonly first examine the whole sample as it is received and observe the types of grains and particles. Recording a general impression of the material is normally done at this time. It is not uncommon to observe foreign materials in soil samples, such as fibers, metals, paint, glass, and plastics. These objects can have important evidential value. In some situations they can be the most important parts of the sample. Plant particles can also be of great value.

With a clean sample, the experienced scientist can identify the rocks and minerals at sight or by using simple tests. In addition, it is possible to observe the texture and coatings on the surface of the grains. Properties of grains such as shape, degree of rounding, weathering, inclusions, color, and polish can be observed and recorded. However, the samples may be so different on first examination that further work is not useful because a determination of common source is ruled out.

Figure 4 Forensic scientist using a stereo binocular microscope to identify particles in a soil sample.

The Petrographic Microscope

Petrographic microscopes have a rotating stage and a polarizing filter under the stage that transmits light vibrating usually in a N-S direction (front to back). Above the stage a second, removable polarizing filter is placed in the tube of the microscope. It transmits light usually in an E-W (left to right) direction. When the upper filter is inserted, light is blocked from passing through the microscope. However, an anisotropic mineral on the stage will cause the light path to be altered, thus making the mineral visible. Isotropic minerals and glass remain dark. Many methods are available to the examiner that permit the identification of minerals and rocks using this type of microscope. The instrument is most important in the identification of the relatively uncommon heavy minerals, after they have been separated from the common light minerals (Figure 5).

Refractive Index

The index of refraction of a transparent material is the ratio of the velocity of light in a vacuum, normally considered to be 1, to the velocity of light in the material being analyzed. Thus a refractive index of 2.4553 means that light travels 2.4553 times as fast in a vacuum than in the transparent material. The measurement of refractive index is one of the most important methods for the study and comparison of glass. Glass appears in a wide variety of crimes such as automobile accidents, breaking and entering, and assault with broken bottles. Today, most forensic laboratories use the semiautomated refractive index instrument GRIM 11 for glass identification. These instruments can produce refractive indices to 0.00007 (Figure 6).

Cathodoluminescence

The instrument used for cathodoluminescence is a lumino-scope that is attached as a stage on a light or a scanning electron microscope (SEM). The specimen, for example, mineral grains or a thin section, is bombarded with a beam of electrons generated by the instrument. When the electrons strike the surface of the specimen, an optical luminescence is

produced, which is seen as a display of colors. The colors and their intensity depend in large part on very small changes in the concentration of trace impurities, the minerals present, and the location of the trace impurities in the structure of the minerals. Thus, the method has wide application in determining or observing a variety of differences in mineral grains that otherwise appear similar.

Scanning Electron Microscope

The SEM has a wide range of magnifications, generally from $25\times$ to over $650\,000\times$, and can record objects as small as 1.5 nm. The depth of field is very large, and most SEM pictures have an excellent three-dimensional appearance. The magnification settings are easily changed, thus facilitating the study of the appearance of the surface of a grain from very low to very high magnification. The presence of very small fossils that were not previously known in a given soil can now be detected during routine examination. Surface features of individual mineral grains such as quartz can be seen and shown to have many different kinds of scratches, pitting, and mineral growth. Some of these features may be useful in telling us the past history of the individual grain. It is not uncommon to observe other minerals such as clay flakes filling the scratches and thus adding another characteristic that can be useful in comparing the minerals.

When using these powerful instruments in forensic work, one must keep in mind that no two objects are ever exactly the same. No two sand grains are ever exactly alike when studied under the high magnifications of an electron microscope. This is true even if they have been side by side for the past million years. Observations made with these instruments can be very useful for establishing similarity or dissimilarity between samples. SEMs also have the ability to determine the elemental composition of the particles being examined. This is possible because X-rays are produced when the electron beam of the microscope strikes a target. The SEM can be coupled to an X-ray analyzer. The emitted X-rays are sorted by their energy or wavelength values, which are related to specific elements, and the analyzer produces information that identifies the elements present in the material being viewed. The amount of each element present is determined by the intensity of the emitted

Figure 5 Forensic scientist using a petrographic microscope to identify particles.

Figure 6 Forensic geologist using GRIM 11 instrumentation to determine the refractive index of a glass.

X-rays. Thus the examiner can determine the chemical composition of the individual particle or particles being viewed.

X-Ray Diffraction

X-ray diffraction is one of the most important and reliable methods of identifying the composition of geologic, soil, and other crystalline substances. The sample is analyzed by passing X-rays through a crystal and measuring their angle of the diffraction as they exit. Each crystalline material has its own distinctive X-ray pattern. The X-ray diffraction pattern of a sample is controlled by the internal structure of the specimen. The diffraction pattern can be collected on film, on an image plate, or by using an electronic detector. The interpretation of X-ray patterns under normal situations is a comparatively simple matter.

Among the strong points favoring the use of X-ray diffraction patterns is that they record the crystal structure. If two substances, diamond and graphite, were analyzed chemically, they would be identical because both are composed of pure carbon, but X-ray diffractograms of the two minerals are quite different. X-ray diffraction is now used as the principal tool in the identification of clay minerals. The chemical composition of clays generally tells us very little as to the nature of clay substances, but the possibilities of identification of clays by X-ray diffraction are almost unlimited (Figure 7).

Chemical Methods

There are a large number of instruments and methods that measure the chemical composition of organic and inorganic materials. There are times where these methods can be very useful and provide valuable information. For example, the chemical composition of glass is often a valuable addition to the optical and physical properties. Identification of organic compounds such as a fertilizer in a soil adds a whole new dimension to the list of properties used in determining comparison.

Methods for determining the amount and kind of elements in a sample may rely on the fact that, as one of its properties, an element selectively emits or adsorbs light. This is the basis for emission spectroscopy and atomic adsorption spectrophotometry. Neutron activation analysis

Figure 7 Forensic geologist using an X-ray diffractometer to identify minerals.

is a nondestructive method. Organic compounds contain carbon and their identification requires different methods. There are several techniques for separating out the various compounds in a mixture. Generally, these methods depend on the relative amounts of the gas and liquid phases of a compound under fixed conditions. That proportion is a characteristic property of each compound. Compounds that more easily enter the gas phase will disappear from a given location more quickly than more stable substances. The rate at which the more volatile substances depart (and hence the distance they move away over a given time interval) allows them to be identified and separated from other compounds. These methods are generally called chromatography. Identification is also done using spectrophotometers, which measure the light-adsorbing properties of a compound. Mass spectrometers have the ability to uniquely identify compounds if analyzed using proper laboratory procedures. This instrument bombards the sample with high-energy electrons, causing the molecules to lose electrons and become positively charged. This is an unstable state and the molecules immediately break up into fragments. The instrument then passes the fragments through an electric or magnetic field where they are separated according to their masses. This permits the specific identification of the atoms in the sample because atomic mass is a unique property of each of element.

The Future of the Science

The last several years have witnessed a tremendous increase in both the quantity and the quality of forensic examination of soil and related material. The future will depend on how well we address a series of issues that include the following:

1. New methods are being developed that take advantage of the discriminating power inherent in earth materials. The opportunities appear to lie primarily in quantitative mineral identification. For this reason, the development of quantitative X-ray diffraction techniques that will provide quantitative data on the mineral composition of a sample would seem to be an important direction for research.
2. Considerable effort must be devoted to defining appropriate sampling methods and the training of those who collect samples. Communicating to law enforcement personnel the potential evidential value of soil and related material is particularly important, because unless the evidence is collected there will never be an opportunity for forensic examination.
3. There is a tremendous need for studies that attempt to demonstrate the diversity of soils. Such studies provide the opportunity for establishing worthwhile information on the distribution of the various soil types. The information should be made available on databases and widely distributed.
4. There must be a continuing effort at all levels to improve the qualifications of examiners in forensic geology.
5. A problem has developed that results from the availability of new instruments that provide increasingly detailed measurements or observations, such as the SEM. These

instruments are capable of discriminating between individual grains. When you discriminate between individual grains, you lose the ability to say that the sample being examined was once part of, and thus had a common source with, another sample. When this is done, the whole concept of comparison is eliminated and the evidential value is lost. The forensic geologist must choose methods that provide the maximum discriminating power between samples without falsely excluding samples that are, in fact, associated.

The real future of the science lies with education. Investigators and evidence collectors must be taught that earth materials can make a major contribution to justice if they are properly collected and studied. The real challenge in all criminal investigations is the production of the best evidence by the most skillful and objective people to serve the cause of justice. Our system of justice is still run by trained advocates (judges and lawyers). Those who the courts honor by soliciting their professional opinions, the expert scientific witnesses, must provide evidence to the highest scientific standards. If they do not do this, the advocates may find ways to remove expert testimony, and then we would return to a judicial system in which the only admissible testimony comes from human witnesses reciting their stories from memory.

The Use of Macroscopic Plant Remains in Forensic Science

J H Bock, University of Colorado, Boulder, CO, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

Forensic botany applies the knowledge and techniques of plant science to legal matters. Here, the term macroscopic plant remains is given to those plant materials not included within forensic palynology or microbiology. Research centered on spores, pollen, and certain microorganisms is well developed and will not be discussed here. For decades, these materials have been used successfully by archaeologists, geologists, anthropologists, and botanists to determine the cause of death for prehistoric or modern humans.

Recent articles show the efficacy of forensic mycology as an important tool for forensic scientists (Page, 2011). Medical mycology is a highly developed field, but except for attention to some psychoactive fungi, this subject matter has not been fully used by investigators.

One of the early documented cases of forensic botany connected with macroscopic plant materials was the suicide death of Socrates. Plato described the death of his mentor as he attended the legally imposed suicide of Socrates. He was convicted of corrupting youth and disrespecting the state religion. Because Socrates was of high social standing, he was allowed to choose his own manner of death. He selected a deadly tea made from poison hemlock (*Conium maculatum* L.: Apiaceae). In Plato's *Phaedo* (Plato and Gallop, 2009), we read of Socrates' symptoms after he drank the fatal brew. This narration agrees with contemporary descriptions of poison hemlock's effect on humans (Lewis and Elvin-Lewis, 1977).

From that time to this, in most of the world's societies the knowledge of plants' effects on humans has appeared in courts (Simoons, 1998). Forensic botany became accredited in the courts of the United States in the trial of Bruno Hauptman who was accused of kidnapping and killing Charles and Anne M. Lindbergh's baby son in 1932 (Graham, 1997, 2006). Arthur Koehler, a wood anatomist with the US Forest Service, matched the wood from the ladder used to get into the second floor Lindbergh nursery with wood from Hauptman's attic. Hauptman was convicted of the crime and executed. The US Federal Bureau of Investigation called Koehler's evidence 'critical.' This crime also resulted in kidnapping becoming a federal offense.

Legitimizing Botanical Evidence

Historic Justification

In trials concerning major crimes, a forensic botanist sometimes is asked whether botanical science has the appropriate scientific background to be relevant. Here facts concerning the history of botany can be presented. The ancient illustrations of plants in herbals have served as guides to medicinal properties of plants including poisons for thousands of years. Another answer to such queries is that botanical science is at least as old as the joining of the printing press, invented in the 1400s, with

the appearance of light microscopy (early 1600s). The early books of note include Robert Hooke's *Micrographia* (1665), Marcella Malpighi's *Anatome plantarum* (1675 and 1679), and Nehemiah Grew's *Anatomy of Plants* (1682) that showed the properties of plants and plant cells.

Evidence Tests

When a judge questions the efficacy of botanical evidence, legal tests must be taken and passed by the forensic botanist. These tests were inspired by recognition that 'junk science' had found its way into courtrooms and was being passed off as accurate 'scientific' evidence. This problem is reviewed and clearly attacked in a recent report from the US National Academy of Sciences (USNAS, 2009). Two legal tests are used for the admissibility of scientific evidence. The first and less rigorous one is the Frye test, which originated in 1923 (United States v. Frye, 293 F. 1013. D.C. Cir. 1923). Here a judge must determine whether an expert's methodology is 'generally accepted' by others in the scientific community. Because many arguments arose about the concept of 'generally accepted' and because of concerns from the science community at large, a second, more rigorous test called the Daubert Challenge is now in place (US Supreme Court case, Daubert v. Merrell Dow Pharmaceuticals, Inc., 509 US 579, 1993). The Daubert Challenge is a hearing conducted before the judge of a case where the validity and admissibility of expert testimony is challenged by opposing counsel. The expert scientist is required to demonstrate that his or her credentials, methods, and reasoning are scientifically valid and can be applied to the facts of the case. Forensic botany usually is readily admitted, unlike certain other kinds of evidence.

General Usage of Forensic Botany

Forensic botany tends to be underused in criminal investigations, perhaps because too few botanists are involved in the field and because most other forensic investigators, such as medical examiners and coroners, have educational backgrounds lacking botany.

DNA Evidence

Trends occur in science. For example, in forensics the use of DNA evidence has become especially important because of its power to identify individuals of the species *Homo sapiens*. DNA testing at present is time-consuming and costly, although this is changing. Sometimes unnecessary DNA testing is performed because of its overstated efficacy. DNA patterns have proven invaluable in the identification of individual humans and have shown the innocence of some. However, comparable genetic information is known for a very few of the 300 000 known

species of higher plants. In almost all cases, using DNA to identify a plant species is a waste of time and money. However, Coyle (2005) has summarized well the uses of plant DNA's value in forensics, especially in cases involving suspected drug plants. When forensic questions center on an individual plant, such as a specific plant associated with a particular crime, DNA identifications can be powerful (Graham, 2006). A case in point would be recent attempts to have a piece of an angiosperm identified to order or family, not species, where costs became prohibitive. Funding often is limited, especially for defense experts in cases where the suspect does not have a great deal of money.

Botanical Applications

The applications of botany to forensic investigations can involve almost any aspect of plant science (Lane et al., 1990). The three subdivisions of botany to be discussed here are:

1. plant anatomy, the study of plant cells and tissues that contain them,
2. plant taxonomy, a subdivision of plant systematics dealing with correct identification of a species, and
3. plant ecology, the relationship between plants and their environment.

These will be discussed in order. In the discussions, case examples, without exception, are based upon personal experience.

Plant Anatomy

Plant anatomy owes its origin to the invention of the light microscope. Hooke's (1665) discovery of plant cell walls in his early drawings remains timely and accurate. The value of food plant cells as forensic evidence in stomach contents depends on the nature of cell walls. Cellulose, the structural material, is undigested by the human digestive tract. Even though the living contents of a plant cell can easily be destroyed, the shapes and sizes of the cellulose cell walls remain remarkably constant during their passage through the human digestive system.

Plants in diets

Browsing and grazing materials in animal diets have been studied by zoologists in many ways, leading to better management of domestic livestock and wildlife (Borchichevski, 2009; Perez-Barberia and Jordan, 1998). Human food plants have been largely ignored except for those scientists studying preserved human remains. For example, the diets of the bog people from Europe, Eurasia, and North America are well studied. Here, scientists reconstructed diets of prehistoric people using remnant plant material associated with preserved human remains. Also, palynology's role, as reported elsewhere, has been highly significant in this work.

The initial challenge in identifying food plants in the human digestive tract came with the knowledge that cell sizes and shapes found in ordinary food plants were not cataloged. Sometimes closely related plants show similar cell patterns

such as apricot and peach flesh (Figure 1). However, an examination of these two photomicrographs shows apricot's distinctive crystals that peaches lack.

Case: This case came as a request from a medical doctor who was an assistant coroner and professor of pathology at a medical school. He wanted to know the plant food contents of a victim's last meal. He sent prepared slides with samples of her stomach contents. Based upon experience in preparing laboratories for courses in plant anatomy, some cells were identified as coming from certain foods.

The victim's last known meal differed from some of the food plant cells present in her stomach contents. This meant she had had another meal before her death; and she would not have done so alone. This suggested her fellow diner could have been her killer. He was. He later confessed to her murder (Sachs, 2002).

Plant cells in the stomach

The above case led to an ongoing collaboration with David O. Norris, comparative endocrinologist and expert in vertebrate physiology, including that of humans (Bock and Norris, 1991). Botanical knowledge alone is insufficient in investigations dealing with human digestion. Once food is swallowed, digestion proceeds in the stomach where the food is immersed in an acid bath, primarily HCl, and subjected to shaking through involuntary muscle activity. Stomach digestion varies in duration, varying in time from less than an hour to as long as 4 h. At its conclusion, the chyme passes through the pyloric valve into the small intestine. This pyloric valve or pyloric sphincter closes at death. This means the stomach contents are held in place until the stomach is subjected to further trauma or the stomach wall decays. Stomach contents sometimes yield important information about time of death.

Case: Several years ago, two young women disappeared on the same January night from the vicinity of a ski resort in the Colorado Rockies. They bore superficial resemblance to each other, but were not acquainted. One young woman's remains were discovered 3 days later along a nearby highway. The following June, the second young woman's body was found in a melting snow drift beside a minor road. The authors were sent the stomach contents of these victims. The stomach contents of the two showed they had eaten similar foods shortly before they were killed by gunshots to the upper torso. In this case, the plant foods were associated with Mexican cuisine, a great favorite with people in the area (Figure 2). The distinctive cell shapes and sizes of the tomato skin and chile pepper seed coat are components of such foods.

Figure 1 Left picture: peach flesh at 10 $\times$; vascular tissue cells similar to those in apricot flesh (see right picture). Right picture: apricot flesh at 10 $\times$; note crystal inclusions not present in peach flesh (see left picture).

Figure 2 Chile pepper seed coat at 25 $\times$ (left). Tomato fruit epidermis at 10 $\times$ (right).

Research

An investigation was done to determine the effects of stomach digestion on plant food cells. Clumps of food plant cells were suspended in HCl solutions approximating those found in human stomachs. The vessels containing the suspensions were placed in a 37 °C water bath stationed on a shaker and left for up to 24 h. No changes occurred in cellulose wall shape or size. Subsequent work demonstrated that the cellulose of plant cells maintains its shape regardless of other processing treatments including freezing, boiling, and roasting (Bock and Norris, 1997).

Methods based on research

Many different food plant cells were measured and a guide prepared (Bock et al., 1988). Today, digestive tract specimens are identified using low power microscopy and a photographic record is taken of the findings (Figure 3). The photos here are of the pulp of an olive. The scanning electron microscope shows more clearly the oil droplets common to olives, but this more expensive technique is not necessary for food plant cells in our experience. This sort of photographic evidence plus verbal testimony has been used in many homicide investigations. When in doubt about a food plant's identity, samples of suspected foods are purchased, ground, placed on microscope slides, and compared with the unknown (Ruzin, 1999; Sass, 1958).

Case: An incarcerated person was murdered in a prison. The suspects in the case were questioned about when they had last seen the victim alive. Was it before or after the 5 p.m. dinner hour? Dieticians in places of confinement such as hospitals and prisons record menus. The last food plant materials in the victim's stomach were from the mid-day meal, not dinner, showing certain inmates were not telling the truth.

Case: Sometimes food plant cells found in human feces can be used as evidence in court. Plant cells from fecal evidence in a rape-homicide were pivotal in a trial. Fecal matter from the victim and from the victim's and suspect's clothing was compared. These data, when presented in court, agreed in kinds of plants and the relative frequencies of the specific cell types. These data were highly significant in the conviction of the suspect (Norris and Bock, 2000, 2001).

Plant Taxonomy

Plant taxonomy is a subdivision of plant systematics that deals with assigning an accurate scientific name to a plant. In order

Figure 3 Olive pulp at 25 $\times$ (left); oil droplets and crystals present. At 280 $\times$ magnification (SEM, right) oil droplets are more distinct.

for the name to be current it should adhere to the most recent rulings of the *International Code of Botanical Nomenclature* (McNeill et al., 2006). Such matters are treated each 6 years at International Botanical Congresses (<http://www.abc2011.com>) by systematists and other botanists from all over the world. Their sessions are always interesting.

Plant identification is the most commonly used tool in forensic botany at present. With such evidence, a victim can be linked to a suspect, a suspect to a place, and a vehicle linked to a suspect, a victim, or both.

Collection of evidence

The collection of plant material for use in criminal investigations differs from techniques taught in plant systematic courses. Forensic collections are assumed to be legal evidence. Such materials need to be collected, if possible, either by officers of law enforcement organizations or by a botanist in the presence of officers. Rules surrounding evidence are strict. When significant vegetation is collected, a chain of evidence must be established at once. Notebook records of time and place and case numbers are required. It is wise, but not required, to assign your personal case number that will be linked to the number that will be used in court. This information must always remain attached to the evidence. Each person in possession of evidence must be clearly documented as the evidence passes among those involved in a case.

Plant collections should be placed either in paper or cloth bags unless pollen analysis also is to be undertaken. Bags need to be the smallest size to accommodate the material. Evidence can be stored in laboratories or evidence lockers for long periods of time, even years. Evidence rooms always are short of space, so economy of collection without minimizing the value of the specimens is essential. Plastic bags, glass jars, and tin cans are unacceptable for long-term storage because they encourage decay.

Identification of specimens

Plant evidence comes from whole plants or plant fragments. It is helpful to know where the plant grew so identification can

be narrowed. For example, it is much better to start using a region-specific scientific flora such as *Colorado Flora Eastern Slope* (Weber and Wittman, 2001) than first consulting *Flora North America*, although you might want to check your identification in the latter or in other floras. The more restricted the flora, the easier the identification becomes. Specialty keys are especially helpful, for example, *The Cacti of Arizona* (Benson, 1969) or *Illustrated Keys to the Grasses of Colorado* (Wingate, 1994). Try to avoid floras prepared for the tourist trade because they sometimes lack scientific rigor.

Paleontological guides to leaf fossils also can be a short cut to contemporary tree and shrub identification.

Plant collection at crime scene

In early stages of an investigation, it may be necessary to characterize the general vegetation of a crime scene. This is best done by a botanist accompanied by an officer who is familiar with the site. If the botanist has familiarity with the general area, leaves, flowers, fruits, seeds, or pieces of bark make sufficient floristic samples. For general collections, more than one species can be put in the same collection bag. If plants require further identification in the botanist's laboratory, larger specimens are taken. This often is necessary for vegetative (i.e., specimens not in flower) Poaceae and Cyperaceae. On the collecting bags or on attached evidence tape, record the date and global positioning system (GPS) location of the collection plus the case number. Also, note this information in a bound notebook.

Collecting plant material from clothing

These items should be collected with forceps. Paper coin envelopes are suitable for storing individual samples. Be sure each envelope is labeled with the case number, date, and place. Be as specific as possible. Place only one species in an envelope. Often these sorts of collections will require laboratory work. You may have a few seeds, a fragment of moss, or partial tree leaf that cannot be field identified. Be sure to note which article of clothing and on what place the specimen was found. For example, the label could read the 'right rear pocket of mustard-colored Bermuda shorts' or 'inside sock near toe.'

Case: A rape-murder victim was found on a golf course in the Caribbean. This course, like many in warm climates, was covered in Bermuda grass (*Cynodon dactylon* (L.) Pers.: Poaceae) a plant native to East Africa. The head groundsman took special pride in the strain he had developed for the course's greens. This grass strain appeared almost hair-like. The clothing and shoes of one of two suspects were examined for plant fragments. Pieces of this special strain of Bermuda grass were found in the shoes and socks of one suspect, and none were found on his Bermuda shorts or his shirt. This was used to show that he had been at the golf course on the night in question but he had not participated in the rape and murder because no grass fragments were found on or in the clothing covering the upper portion of his body. Due to this circumstantial evidence he was spared the death penalty, although he confessed to being a witness to the crime.

Collecting plant material from exterior of vehicle

Usually this is done on impounded vehicles. With an investigator, a botanist collects materials from the underside of the car. Places to be collected include the tire treads, wheel wells,

fenders, bumpers, window wiper slots, and the undercarriage itself. For small plant objects, the collection is made with forceps, using paper coin envelopes for storage. Larger pieces of vegetation may be attached to the undercarriage and stuck in the wheel wells, and larger paper bags are needed. See section 'Collection of Evidence' for label instructions.

Collecting plant materials from inside vehicles

Almost all plants and plant fragments will be small. For small objects, the collection is made with forceps and paper coin envelopes. Places where plant materials are found include on and under floor carpets and seat covers, in the grooves on pedals, behind seats, in the boots (trunks), and under the bonnets (hoods). Investigative departments often possess vacuum sweepers for evidence collection from carpets in homes and in vehicles. Try to avoid having these machines used for materials you must examine. They pulverize the plant pieces.

Case: A man was suspected of having killed his wife. Her body was found in the Rocky Mountains of Colorado at an elevation of just over 3000 MASL. The man's truck was impounded and vegetation specimens were collected from it. The suspect claimed that his truck was used only in his work on the eastern Colorado plains and was not taken to elevations above about 1880 MASL. Investigators visited the place where the victim's body was found and sampled a reference collection of vegetation. They also collected the vegetation around the couple's home and surrounding grassland. A comparison of the vegetation of the two collection sites with the plant fragments found on and in the vehicle showed clearly that the truck had been at the higher elevation. This was not conclusive evidence that the truck had been in the exact spot at 3000 m where the body was found because there were nearby canyons that held similar vegetation. This circumstantial evidence showed that the suspect lied about where the vehicle had been. This, plus other evidence, led to a murder conviction.

Plant Ecology

Ecological methods have considerable value in certain kinds of investigation. A plant ecologist must be aware of plant succession patterns in the region related to a crime. The plants indigenous to the region in question should also be known. This knowledge often is used to help locate clandestine graves. Recently buried animals, including humans, enhance growth and greenness of the vegetation above the site and this can be evident once decay has proceeded. The late Bombeck (1976) wrote a book entitled *The grass is always greener over the septic tank*. As this title implies, buried decaying matter supplies fertilizer to the plants growing above, and gives them a distinct appearance in comparison with surrounding vegetation. Depending upon the environmental conditions of a burial site, these sorts of clues can persist for as short a time as a few weeks in tropical and semitropical damp environments, but they can remain in place much longer in cold and dry habitats. Another ground level indicator occurs as decay proceeds. Subsidence of the topsoil takes place due to the reduction in overall volume of the remains. In recent years, this has helped in the search for mass graves of war victims (Brown, 2006).

Colonizing plant species can indicate where an organism was deposited. These are the plant species, often short-lived,

that thrive on bare ground. In time they tend to disappear or be greatly reduced in prominence because they are succeeded by other species that compete well with other plants. Succeeding plants also respond to the slight environmental modifications that colonizers engender. In both tropical and temperate areas, this process of species succession can indicate where bodies were buried for many years, even decades after the burial. Also, knowledge of plant phenology can be helpful. Plant parts associated with crimes may indicate the season when an event took place, in contrast to the time when the grave was discovered.

Research on buried bodies

Aspects of decomposition by buried animals have been a topic of research over the last few decades (Sachs, 2002). The most famous of these is associated with the University of Tennessee's Anthropology Department's Forensic Anthropology Center, commonly referred to as the Body Farm (Bass and Jefferson, 2003). Valuable information about human decay processes has come from here.

Necrosearch International is a volunteer organization whose purpose is to search for clandestine graves (Jackson, 2002). The members have learned a great deal from burying pigs on a law enforcement training ground south of Denver, Colorado. The pigs were buried at various times over the past several years at varying depths, sometimes naked, sometimes wrapped in plastic, and sometimes clothed. This activity was named Project P.I.G. (Pigs In Ground). Now, P.I.G. is used extensively in crime-scene training programs.

Necrosearch has succeeded in finding the graves of missing persons in several parts of the United States and abroad. Forensic botany is an integral part of its program. Plant anatomy, plant taxonomy, and plant ecology methods are used.

Necrosearch investigations usually involve teams of specialists. For example, a team comprising a forensic botanist, a cadaver dog handler, and a ground penetrating radar expert could be used to find a missing person. Some of the other experts in Necrosearch include geologists, forensic anthropologists, forensic entomologists, criminal profilers, DNA analyzers, medical pathologists, and ground and aerial photographers.

Education for Forensic Scientists

General Education

There are no specific programs at present for training a forensic botanist. However, higher education institutions ranging from junior colleges to major research institutions offer certificates and degrees in criminal justice, *sensu lato*. Individual specialization within these programs is advised. Such studies can prepare a student to become a law enforcement officer, a para-legal, or a forensic laboratory technician.

Most, but not all, crime-scene investigation courses do not include forensic botany in the curriculum. Courses with botany included have been given to police academy training courses, FBI seminar courses on new techniques in crime-scene investigation and courses for coroners, medical examiners, and criminal lawyer groups. Without exception, these sorts of groups have embraced the techniques of forensic botany (J. Bock, personal experience).

Advanced Degrees in Forensic Studies

Thesis topics that prepare one for work in forensics can be obtained within an advanced degree program. People with PhDs in botany, entomology, anthropology, geology, paleontology, computer science, and most other sciences, along with individuals holding medical and law degrees, can modify their careers in ways to become forensic specialists. Many careers for forensic scientists are linked to local and state forensic laboratories. Alas, the otherwise outstanding national FBI laboratory at Quantico, Virginia, has no forensic botanist on staff. However, major laboratories in other countries including New Zealand, Australia, England, Canada, and Great Britain are staffed with forensic botanists.

Acknowledgments

I am especially indebted to Dr. David O. Norris, Dorothy C. Sims Esq., and the Hon. Haskell Pitluck for fostering justice through science.

Introduction

Forensic scientists use insects to address questions of legal relevance. This discipline is called 'forensic entomology.' The approaches taken in forensic entomology and Quaternary science are similar: entomological material is interpreted in the light of ecological and biological information. The morphology of insects and sometimes other arthropods is used to identify species; knowledge of life cycle durations and habitat preferences is used to interpret aspects such as length of colonization and time since death. This interpretation becomes part of the evidence in the court. Amendt et al. (2007) proposed standards and guidelines to ensure good forensic entomological practice.

Forensic entomology can be classified into several areas. Matters relating to time since death of a person or animal, where entomology is used to determine postmortem interval (PMI), and the likelihood of neglect or abuse are considered by criminal courts. Cases utilizing forensic entomology in the civil courts tend to relate to urban entomology, such as insect infestations of structural material or complaints about insects in food and stored products (Gennard, 2012).

In urban environments, insects which are perceived as a nuisance, such as bees, wasps, and flies, can lead to court cases. For example, the stable fly *Stomoxys calcitrans* (Linnaeus) can reduce milk production by a small percentage. Thus, its presence has an economic cost to dairy farmers as well as engendering dislike because this species bites humans, cattle, and even dogs. Bad farm management or poor hygiene, which encourages the presence of such flies, is likely to result in a civil case to force the removal of the nuisance. Interestingly, in the tropics, an increase in populations of *S. calcitrans* has been positively correlated with rises in precipitation and temperature. Their presence can also have indirect forensic relevance. Goff (1991) considers *S. calcitrans* an indoor species on the island of Oahu, Hawaii. Therefore, from a forensic perspective, larvae of *S. calcitrans* on a body found in the open in Hawaii would indicate that the body had been moved.

Evidence of insect infestation of building materials can also have legal implications. For example, purchasers could sue for damages against the estate agent, solicitor, surveyor, and professional timber specialist, on the basis of lack of information, if they found that a house survey failed to record signs of insect infestation, once they had purchased the house. The basis of such a case would be that if the buyers had known about a prior (albeit treated) infestation by, for example, the common furniture beetle (*Anobium punctatum* DeGeer), which the surveyor considered unlikely to recur, they would not have continued with the property purchase. In such instances, the entomological information would be the subject of the case. As in this hypothetical example, provision of entomological advice to solicitors about urban entomological issues constitutes a further, and often major, aspect of the work of the forensic entomologist.

Stored product pest civil cases are usually related to food infested by insects: weevils in biscuits, or the remains of flour moths in a sack of flour. Adult cockroaches are frequently the topic of forensic investigations in buildings such as hotels and hospitals. However, in Iran cockroach nymphs of *Blatta orientalis* (Linnaeus) have also been recorded from excised human viscera (Tüzün et al., 2010).

Any insect, or indeed other arthropod, can be of forensic value as a proxy to determine what happened in the past. It has either to be the subject of evidence in court or provide information that assists in interpreting a legal matter. Some insects can be present by chance and hence are of no legal importance, while others are there because of the presence of favorable food, which may include dead bodies.

Insects for which a corpse provides both food and a habitat are termed necrophages. Insects or other arthropods such as spiders, present because they feed upon the adults, larvae, or eggs of the necrophages, are termed predators. Some species can consume both the corpse and organisms living on the corpse; these are termed omnivores. The insects present, as it were, by chance are termed accidentals. Such carrion-related species are drawn to the body either by decomposition odors alone, or they are attracted by the presence of other insect species inhabiting the corpse.

Research on both scavenger species such as the Turkey Vulture and those insects causing myiasis (such as flies colonizing living organisms) has shown that they are olfactory foragers, attracted by the smell emanating from the food source. The nature of these attractants to the corpse is a matter of ongoing research.

The odor profile of decomposing bodies changes over time, both in terms of the odors present and of their proportions. Different insect assemblages are attracted to a body during the various stages of decomposition. Thus the presence of different insect species on a corpse provides evidence of the length of time since death. The stages of decomposition through which a body passes are based on visual descriptions. They are fresh, bloat, active decay, advanced decay, and the dry stage – skeletal remains (Table 1).

Speed of decomposition varies with environmental conditions.

Work by Statheropoulos et al. (2005) explored the decomposition volatiles of two individuals estimated to have been dead for between 3 and 4 weeks. The greatest contributors to the odor profiles were dimethyl disulfide, toluene, hexane, benzene, 1,2,4,trimethyl-2-propanone, and 3-pentanone. However, little was known about the origins of the deceased and the influence that the cause of death had on the odors revealed.

Initial chemical attractants of *Calliphora* species include dimethyl disulfide and dimethyl trisulfide: chemicals that have been shown to illicit a positive electrophysiological response from species such as *Calliphora vomitoria* (Linnaeus; the Holarctic blue bottle fly). Vass et al. (1992) considered that after 1285 accumulated degree hours (ADH), volatile fatty

Table 1 Stages of decomposition of a body

Visual features of a decomposing body	Decomposition stage
No obvious change from normal; no odor	Fresh
Body is swollen and there is some body fluid seepage; livor mortis (looks like expansive bruising) may be obvious. Later in this stage the skin may split. Some odor is noticeable	Bloat
Strong odor; the body has deflated and often the head has become defleshed in places and the eyes have sunk into their sockets	Active decay
Soft tissue covering the skull has become reduced in quantity, often there is only a small amount of tissue in the abdominal region. The odor is less obvious	Advanced decay
Bones, hair, and dried skin remain. There is no noticeable odor.	Skeletal remains

acids such as propionic, valeric, and butanoic acids fall to background levels, thereby providing an explanation for the reduction in the number of insect species attracted to the body in the last stages of decomposition.

Insect Life Cycles

The key insect species used by forensic entomologists are those that feed directly on the body or food, as they provide a means of determining how long the body has been present at a particular location, or how long the food has been infested. Determination of the life cycle duration and body size (e.g., length) in each of these stages is a key tool in forensic entomology calculations. The majority of relevant research is laboratory-based. The average time spent in each of the life stages at fixed temperatures has been calculated, along with the average length (or width) of the larvae in that stage. This information is then interpreted according to the life cycle stage found at a crime scene, or recovered from a particular situation that the forensic entomologist is being asked to examine. There is a specific physiological energy budget for each stage. Speed of insect growth is related to temperature, so it is possible, based on our knowledge of insect larval growth rates, to determine the contribution towards the total physiological energy budget provided at the crime scene in each hour or day. The total of these hourly or daily contributions (ADH or accumulated degree days) reflects the total amount of time taken to reach a given stage in larval development, and hence time since death or colonization by the specific larval instar on the body. Key morphological features such as spiracle shape, structure, and slit number that relate to identification of the life stage are used to determine species and life cycle stage.

Both beetles (Coleoptera) and flies (Diptera) are insect orders which contain forensically relevant species that have a complete life cycle with morphologically distinct stages: egg stage, larval stage, pupal stage, and adult stage. The egg stage provides some indication of species but cannot easily provide anything other than a broad time frame for the purposes of PMI determination.

Calliphoridae (blowflies) have three larval instars. The first (LI) is the result of hatching from the egg and continues until the next molt. The second instar larva (LII) exists between this

molt and the next. The final instar (LIII) exists between the periods of second molt and pupation, although the cuticle (outer skin) is retained and tanned and becomes the puparium in which the fly pupa subsequently forms.

From the perspective of species relevance as proxies in a Quaternary context, it is likely to be the remnants of larval spiracles on puparia that provide evidence useful for environmental reconstruction. To determine time since death (PMI), the time to reach the oldest larval growth stage found on the body is used as an estimate. Some entomologists, in situations where the temperature is fairly consistent at the scene, use maggot size (length or width) to determine the time since death, assuming that food is not a limiting factor as it will influence the size of the maggot (Figure 1(a) and 1(b)).

The insects of major importance in forensic entomology are discussed under their family headings below. The list is split into two; the majority of families discussed have terrestrial forensic relevance and are flies or beetles (Diptera or Coleoptera). The last two families, one a Diptera and the second from the Trichoptera (caddisflies), have aquatic forensic relevance but have also been shown to have a valuable role in Quaternary science. The specific insect species that visit a body will vary depending upon their habitat and biogeographic range.

The Forensic Value of Members of Specific Insect Families

Diptera (Flies)

Calliphoridae (blowflies)

A number of members of the Calliphoridae are valuable forensic tools. In particular, *Calliphora vicina* Robineau-Desvoidy (the European blue bottle fly) and *C. vomitoria* are species commonly used to determine the time of death.

These species are primary invaders and readily colonize the body after death. *C. vicina* is especially associated with urban environments, although its territory can be expanded into less developed areas close by. *C. vicina* is valuable, as it is found in a range of habitats and has even been noted on a body in a cave where the temperature was consistently 5 °C.

Calliphora vomitoria is also a primary colonizer but tends to be the first species to arrive at bodies found in more rural environments. This species is attracted to decomposition odors such as the sulfides – for example, methyl disulfide, methyl trisulfide, and methyl tetrasulfide (Gennard, unpublished data).

Other *Calliphora* species of note include *Calliphora hilli hilli* Paton (a subspecies of Hill's brown blowfly) and *Calliphora stygia* Fabricius (the common brown blowfly), species that are found in Australasia. Their significance is the result of the studies undertaken because these species are often causal agents of myiasis (parasitic infestation by fly larvae) in sheep. Therefore they have an economic significance.

A number of *Lucilia* species (green bottle flies) also have forensic significance and have been found to colonize bodies. They include *Lucilia sericata* Meigen the common green bottle fly, *Lucilia caesar* (Linnaeus), *Lucilia richardsi* Collin, *Lucilia illustris* Meigen, and *Lucilia cuprina* (Wiedemann). The rate of egg laying (oviposition) in *L. cuprina* has been shown to increase where there is opportunity for the flies to make contact

Figure 1 (a) The puparium of the fly. (b) The beetle pupa.

with water (Barton Browne, 1962); so environmental conditions are significant.

Lucilia sericata (called *Phaenicia sericata* in North America) can be an initial colonizer where temperatures are sufficiently warm (Horenstein et al., 2010). It tends to like warm, sunny habitats and prefers to lay its eggs on carcasses in direct sunlight. Therefore, it will be the colonizer of bodies found in exposed conditions such as open fields or on moors, rather than where shade is provided by canopy vegetation.

Protophormia terraenovae Robineau-Desvoidy (the northern blowfly) is found early in spring in the United Kingdom and is cold-tolerant. It is therefore, an early colonizer, and its range has recently expanded into other locations in Europe. Significantly, the pupal cases (puparia) of this species are found in direct association with the body, rather than some distance away from it, because pupation (the process by which the larva becomes a pupa) takes place on the body. *P. terraenovae* was recorded from the Holocene in Greenland, and is very much more significant in Scandinavia as a forensic indicator than in other parts of Europe.

Phormia regina Meigen (the black blowfly) is recorded from bloat stage in forests in western Poland (Matuszewski et al., 2008). The decomposition of pig carcasses is often used by forensic scientists as a proxy for human body decomposition. Field observations of *P. regina* larvae on pig carcasses showed that they lived on the carcasses for a period of 15 days (days 5–20 after death); this is a much shorter period of habitation than that of other blowfly species. Larvae of *L. caesar*, for example, were present from day 3 to day 31, while *C. vomitoria* larvae were present from day 4 to day 38.

The species of *Chrysomya* found on bodies include *Chrysomya rufifacies* Macquart (the hairy maggot blowfly), *Chrysomya megacephala* (Fabricius) (the oriental latrine fly), and *Chrysomya albiceps* (Wiedemann). These species are spreading beyond their historical geographic ranges, presumably as a result of changes in climate. For example, *Ch. megacephala* is now recorded from Spain and Portugal, whilst *Ch. albiceps* has extended its range to colonize Poland, the Ukraine, and Northern Italy. *Ch. albiceps* is considered a secondary invader, where members of the Calliphoridae subfamily are present as primary invaders (Denno and Cochran, 1975). Interestingly, in the warmer months in Argentina, *Ch. albiceps* is thought to be able to limit the number of eggs laid by *L. eximia* (Wiedemann) if the former colonizes the body first (Horenstein et al., 2010).

Cochliomyia macellaria (Fabricius; the secondary screwworm fly) is a primary colonizer. However, its population can be reduced if *Ch. rufifacies* is present on the body at the same time, especially in the later instars. A similar effect seems to occur if *Ch. megacephala* and *Ch. rufifacies* coexist on a body.

***Sarcophagidae* (flesh flies)**

Members of this family are significant in that they will lay live larvae (larviposit) on corpses, rather than lay eggs. Flesh flies are known to have a wide geographic distribution. For example, a study of carrion flies in three areas of the Amazon rainforest by Amat (2010) (flood plain forest, white sand forest, and terrestrial forest) has revealed that Sarcophagidae had the greatest species richness.

In colder seasons of the year, some flesh flies, for example *Sarcophaga africa* Wiedemann, colonize a body after *C. vicina*, but act as the initial colonizer when the weather is warmer. If it has been raining when the body was placed at a location, or where the person died outside, flesh flies may also be the initial colonizer. They can fly in the rain, whereas calliphorids do not (Smith, 1986). So in this sense, sarcophagids, in the absence of calliphorids, are a proxy for a past weather incident.

***Muscidae* (house flies and stable flies)**

Muscidae are flies that are most often associated with feces, urine, and waste material emanating from a body. From a forensic perspective, their value as an indicator is geographically variable. For example, the muscid fly *Synthesiomyia nudiseta* (van der Wulp) was found at corpses during a number of stages of decomposition in experiments in Costa Rica; so it is not specific to a particular stage of decomposition. In experiments conducted in Argentina, it was found only in small numbers in the muscid assemblage and the value of this species as a postmortem indicator has been questioned (Calderón-Arguedas et al., 2005). Muscid flies, for the most part, are species that arrive at a body soon after death when body fluids have been exuded, or later when there has been leakage of decomposition fluid in sufficient quantity to provide them with a suitable food source. In Argentina, Horenstein et al. (2010) found that they were the second most abundant family collected from carcasses. Their presence at crime scenes may also give them a value as an indicator of seasonality.

Flies such as *Musca domestica* Linnaeus (the common house fly) may be equally attracted to decaying vegetable matter and become a pest associated with farming or domestic compost

heaps, which brings them into the realm of forensic entomologists. These flies are also found in restaurants, kitchens, and other warm places.

Members of the genus *Hydrotaea* (dump flies), or its synonym *Ophyra*, have been recorded from corpses by a number of researchers. *Hydrotaea dentipes* (Fabricius) is known from a wide range of habitats including cesspools, decaying plant material, fungi, and carrion, as well as on bodies discovered both inside buildings and outdoors. Larvae of this species (and those considered part of the *H. dentipes* group) hatch from the egg as first instar larvae which are either predators, reducing the number of other larvae present at a location, or saprophagous (feeding on dead or decaying animal matter). This is not true of all species of *Hydrotaea*, since they can also emerge from the egg into the second instar larva. Other species of *Hydrotaea* such as *Hydrotaea rostrata* Robineau-Desvoidy (the black carrion fly) have also been recorded from forensic contexts.

Fanniidae

Forensically relevant Fannid flies, much as muscids, feed on fecal material and areas of the ground or clothing stained by such body fluids. They are not specific to any particular stage of decomposition, although Horenstein et al. (2010) found them in greater numbers in winter and spring than in summer and autumn in central Argentine experiments. Fannid larvae are flattened unlike those of the Calliphoridae, and so are easily distinguishable. They have obvious lateral protuberances.

Fannia species of significance include *Fannia scalaris* Fabricius, the latrine fly. This species is particularly associated with human excrement. The lesser house fly *Fannia canicularis* Linnaeus is particularly recognizable at the egg stage. Its eggs have a modified corion (outer coat), with what appear to be two floats, allowing the eggs to be suspended above the surface of the fluid in which they have been laid. This species too is attracted to excrement and dead bodies of animals and humans, although it has been recorded as feeding on living organisms.

Fannia canicularis is considered to be an agent of urinogenital myiasis and therefore can be an important insect species in cases of suspected neglect. It is recorded as a secondary sheep strike agent in some countries and will infest wool that has been soiled by urine and feces. In forensic contexts, the larvae have been associated with advanced stages of decomposition.

Phoridae (scuttle flies)

This family is called scuttle flies because of the way the adults move across a surface if disturbed. They are extremely small flies, which colonize the body early in decomposition, and have been known from both buried bodies and those that died indoors. *Megaselia scalaris* (Loew) is a scuttle fly species found on bodies indoors as well as outside. It has a recorded lifecycle of 19–22 days at a temperature between 20 and 25 °C and a relative humidity constantly greater than 50% (Leccese, 2004).

Puparia of *Megaselia abdita* Schmitz were recorded as the dominant insect of evidence by Manlove and Disney (2008) in a case where the body was discovered in January. By determining the temperature of the location where the deceased had been found, and relating this to the time taken for the phorid to pass through a complete life cycle at that temperature, it was possible for them to propose a minimum time since death.

The species most commonly found in association with buried bodies is *Conicera tibialis* Schmitz (the coffin fly). This species, once mated, is considered to be able to pass down through the soil to the body, and lay eggs such that the larvae can colonize the body as a source of food (Colyer, 1954). The next generation then re-emerges from the soil.

Members of the Phoridae are also of value as postmortem indicators in winter. For example, *Triphleba autumnalis* (Becker) can be found as larvae on carrion between December and February, although it enters diapause (a period in which growth or development is suspended and physiological activity is diminished) to survive conditions during the rest of the year (Lundt, 1964).

Sphaeroceridae (lesser dung flies)

This family comprises small black flies around 1.5–3.5 mm long, and the basitarsus on their hind leg is short and dilated. Sphaerocerids can be found in habitats ranging from decomposing vegetation and seaweed to organic material in caves or on dead bodies. Smith (1986) considers that they are indicative of the advanced decay stage in response to the presence of fatty acids, but Erzinçlioğlu (1983) recorded them at the start of the decomposition process.

This is an example of the need for specific ecological knowledge about the colonizing sphaerocerid species. Amendt et al. (2010) describe the case of a body sealed into a mine shaft from which they recovered 20 third-instar larvae (LIII) of *Leptocera caenosa* Rondani. This species has a preference for dark, cool habitats such as caves and cellars or similar habitats. It also prefers to colonize bodies at the advanced stage of decomposition. This preference allowed Amendt et al. to estimate a period of 30 days from oviposition to post feeding for this species, which they concluded had colonized the body once it had been placed down the mine shaft.

Piophilidae (cheese flies or skipper flies)

Piophilids of forensic interest are attracted to the active decay and also the dry stage of body decomposition. Members of the family have been found on human cadavers, human excreta, bones, skin, and fur. They are also thought to be present when volatile fatty acids are emitted from the body. Their period of colonization is short, as is their life cycle. Piophilids have been found associated with food materials such as cheese and meat, and one particular species, *Piophilidae casei* (Linnaeus), is called the Cheese Skipper because of this association. Specimens of *P. casei* have even been recovered from Egyptian mummies, so the species has broad forensic relevance.

Russo et al. (2005) determined the duration of each life stage of *P. casei* at a range of constant temperatures (15, 19, 25, 28, and 32 °C). They showed that adult longevity was temperature-dependent and that the net reproductive rate was greatest at 25 °C. Such data is valuable, as it is the basis by which the forensic entomologist determines time since death/colonization.

Sepsidae (black scavenger flies)

Members of this family, commonly called scavenger flies, are associated with bodies at an advanced stage of decomposition. They are small, shiny flies, distinctive because of the constriction in the region of their first abdominal segments. The adults

are distinguished from piophilids or sphaerocerids by their trait of wing wagging as they move. The significance of their presence on the corpse varies because they are also associated with feces. One species, *Orygma luctuosum* Meigen, usually found breeding in seaweed, has been found to be of forensic relevance and its presence on a body provides a link to marine environments.

Stratiomyidae (soldier flies)

These are an indicator of the later stages of decomposition. Larvae of the black soldier fly *Hermetia illucens* Linnaeus, although originally a species native to America, have been recorded on corpses in a number of places and more recently in southern Europe. Larvae of stratiomyids are characterized by having a layer of calcium carbonate over their body surface. This gives the larval body a roughened appearance. It also protects the larvae from drying out. The species has additionally been recovered from drug hauls of cannabis.

Several forensically relevant species with an aquatic life stage also have Quaternary value. Trying to date the time since submergence presents a number of difficulties for the forensic entomologist. In general, a range of species of macroinvertebrates are used, which may include some families of insects. The calculations are based on the proportions of various members of different functional feeding guilds. The main difficulty for the forensic entomologist arises because species that colonize the body will vary both geographically and seasonally. There are some families of insects with aquatic life stages which are particularly relevant. These are discussed below.

Chironomidae (nonbiting midges)

This is one of the families of aquatic insects that have forensic relevance in crime scenes where the body has been recovered from water. These midges are also of value in Quaternary science. Subfossil chironomids have long had a role in paleolimnological research.

One notable forensic case, which characterizes the role of chironomid larvae (Figure 2), is that of the 'red fiber.' Trace-evidence forensic experts were unable to identify a red-colored 'fiber' dried onto a surface of a body recovered from water. In desperation, they showed the material to forensic

Figure 2 Chironomid larva.

biologists. The biologists later confirmed the 'red fiber' as a member of the chironomid family which had become attached to the murder victim whose body had previously been submerged in water (Hawley et al., 1989). The subsequent observation of chironomids on other bodies led to them to be considered a good indication of submergence and of value for the calculation of the submerged interval.

Trichoptera (caddisflies)

A caddisfly assemblage can provide information on the local aquatic habitats, based on their biological and distributional information. As such, they are of use in both Quaternary and forensic science. Caddisflies have been found on submerged bodies (Wallace et al., 2008) and used to determine the duration of time since submergence. The value of the particular families of caddisflies varies with the circumstance (Figure 3).

Net-spinning caddisflies (Hydropsychidae), although of value in Quaternary studies, do not necessarily provide a specific means of determining the postmortem submerged interval. Those species of caddisfly that make their cases from vegetable matter and sand and other fragments can often be more useful. For example, Wallace et al. (2008) used the seasonality and the duration and timing of life stages, including the onset of dormancy, of two species of Limnephilid caddisflies to estimate the time of submergence of a body at a crime scene. These forensic entomologists were able to infer that the body was submerged between late April and late May.

Coleoptera (Beetles)

Histeridae (clown beetles)

Members of this family are often missed in forensic assessments, as they are found beneath the body and tend to be most active at night. They are predators of the fly larvae present on bodies. Therefore, they can potentially reduce the numbers and range of fly species present upon which the PMI can be based.

Figure 3 Caddisfly larva uncased.

The population of Histerids tends to be greatest in the active decay stage of decomposition when fly larvae populations are also large. The distribution of specific species colonizing a body may vary with the stage of decay. Matuszewski et al. (2008), for example, in studies on corpse decomposition in forests in western Poland, recorded species of *Hister* and *Saprinus* as restricted to the active decay stage, while *Margarinotus* species' presence extended into the advanced decay stage as well. In other areas of Europe, the Histerid species, *Hister unicolor* Linnaeus and *Pachylister inaequalis* (Olivier), are most frequently recovered from bodies (Figure 4).

Cleridae (checkered beetles)

Clerid beetles are found on bodies during a range of decomposition stages. They not only consume the remains of cadavers but also prey upon the eggs and larvae of necrophagous flies present there. The family becomes of significance at the later stage of corpse decomposition when members of the genus *Necrobia* can be recovered from the body.

Clerids are also stored-product pests and so may have relevance to forensic entomologists who are involved with stored-product pest cases. They are also the cause of damage to, or found in association with, archaeological finds. *Necrobia rufipes* (DeGeer) the red-legged beetle, for example, was observed on the mummy of Ramses II.

Silphidae (carrion beetles)

Silphids are present on corpses located outdoors. Some will feed on the corpse directly; others will feed on both the corpse and the other insects present on the body, such as the larvae, while others feed solely on larvae of insects such as flies.

There are two Silphidae subfamilies; the Silphinae and the Nicrophorinae. Watson and Carlton (2005) distinguished the importance of these two subfamilies in terms of attraction to size of corpse rather than habitat; Silphinae are found in rural locations and are attracted to larger corpses and hence have a greater value in forensic terms. In part, this may be determined by the food preference of the particular species. Adult *Silpha* species, for example, consume fly larvae, whilst the larvae of this species consume the remains of the body.

Figure 4 Histerid beetle.

Different species of silphid dominate, depending on the habitat type. Nicrophorinae are considered to be attracted to small carcasses and they also vary in the habitat in which they are found. For example, *Nicrophorus humator* Gleditsch, (the sexton beetle) and *Nicrophorus vespillo* Linnaeus tend to be restricted to forests. Michaud et al. (2010) found that *Nicrophorus tomentosus* (Weber), the gold-necked carrion beetle, was present in both fields and forests, although other members of the Nicrophorinae showed a preference for forest habitats (Figure 5).

One of the common silphid species, considered to be a forensic indicator and found on both human and pig corpses in Southeastern Brazil, is *Oxyletrum discicollae* (Brullé; Carvalho et al., 2000). Mise et al. (2008), however, recorded the presence of this species over 126 days, from the fresh stage until the body had entered dry decay stage and fly larvae had left the bodies. In North America, *Necrodes surinamensis* Fabricius and *Oiceoptoma inaequale* Fabricius can be found on the corpse at the same time. They have three larval instars; which specific larval instar is present can most readily be distinguished by using the distance between the dorsal ocelli (simple eyes; Watson and Carlton, 2005).

Dermestidae (skin or larder beetles)

Different species of dermestids are known from corpses in a range of decomposition stages. They are also a cause of damage to museum specimens and an economic pest recognized from dried and preserved food.

Three species are perhaps of particular forensic relevance, and have been recorded from archaeological contexts. These are *Dermestes frischi* Kugelman, *Dermestes maculatus* DeGeer, and *Dermestes lardarius* Linnaeus.

Dermestes frischi is found predominantly in the wild and therefore from outdoor bodies. Drugs present in the tissues of the corpse can be recovered from the larvae and pupa of this species. The advantage of being able to use pupae from some insect species is that they may be recovered many weeks, months, or years after the death or consumption of the material concerned. Therefore, they have long-term value as a forensic indicator. The two other forensically significant species of dermestid, *D. maculatus*, known as the hide beetle, and *D. lardarius*, commonly called the bacon or larder beetle, are also pests of stored products, fur, and other animal products, and are found

Figure 5 Silphid beetle, *Nicrophorus humator* Gleditsch.

on corpses in certain circumstances. Much of the stored product damage is caused at the larval stage when their larvae burrow into material such as wood, hide, or even concrete, in order to pupate in a location safe from cannibalism by other larvae. The adults and the larvae, which have hairs, will consume meat and carrion as well as other animal products. The adults do not consume wood or books as a food source, however.

D. maculatus has been found to be a pest of stored museum specimens. It has also been found when new museum exhibits were examined. The Bristol Mummy, when it was unwrapped, for example, revealed the presence of *D. maculatus* which had attacked the body of Han-Em-Kem-Esi. It appeared that the beetles had become incarcerated in the wrapping, having been attracted to the dead body as it was prepared during embalming, prior to entombment (Figure 6).

Scarabaeidae (dung beetles)

Members of this family are recorded from carcasses, although they may not be present in large numbers. The majority of specimens of this family found on pigs modeling human corpse decomposition have been from the genera *Onthophagus* and *Aphodius*. Michaud et al. (2010) similarly recorded these genera amongst the scarabaeid species captured from the body of a pig, in a Canadian study. They were able to compare the scarabaeids collected from the bodies of pigs in forests and agricultural fields. There was a greater abundance of Scarabaeidae colonizing bodies left in fields than those in forests. The assemblage species remained stable throughout the year, irrespective of the season.

Ururahy-Rodrigues et al. (2008) made a particularly important point about the taphonomic effect that some Scarabaeidae might have. In their work in Brazil, they showed that *Coprophanæus lancifer* (Linnaeus), a scavenger dung beetle, could have a significant effect on the position of the body. This species is necrophagous and feeds its larvae on fragments of the decomposing corpse. It will lay eggs in chambers located near to a corpse, often tunneling beneath it. This behavior can result in postmortem damage to the body, as recorded by the authors, since adult dung beetles bite through the tissue and can actually move the body physically and/or disturb the disarticulated bones.

Figure 6 Dermestid larva consuming flesh.

Nitidulidae (sap beetles)

These are minute beetles, smaller than 6 mm in size, found at the drier stages of decomposition. *Omosita discoidea* (Fabricius) is an example of a sap beetle which may be recovered from a corpse or decomposing pig carcasses at the later stages of decomposition, frequently in the dry stages. Another nitidulid beetle, *Glischrochilus quadripunctatus* Linnaeus, has been found on bodies in autumn where the corpse is in mixed woodland. The latter species has also been recovered from rotting fruit (Figure 7).

Staphylinidae (rove beetles)

Members of this family are found in the environment of the body and feed off both the eggs and larvae of necrophagous species. They, like spiders, can reduce the population of indicators of time since death. They confirm that the body has been in place sufficiently long to attract flies and for them to have laid eggs on the body. Only those species that lay eggs in the soil near the body have a forensic significance for calculation of the PMI. They may be the dominant beetle family present on a body, and in this case reduction in the number of eggs or larvae may result, and this should be taken into account in interpreting the results of the PMI. This is true especially if there is evidence of a missing larval instar in the samples of fly larvae collected; for example, there are lots of instar LI and LIII but few larvae in instar LII. Such a disruption in the sequence of larval instars present on a body is most often considered to be the result of removal of a body from one site to another.

Limitations in the Use of Insects in Forensic Entomology as Proxies

The major limitations to the use of insects for forensic purposes are either

- i. a lack of appropriate data recovered from the crime scene, or
- ii. a paucity of ecological knowledge about the specific insect species recovered from the body in relation to that particular crime scene.

Figure 7 A saprophagous nitidulid beetle (*Glischrochilus* sp.).

The majority of calculations of time since death relate to the larval stage and which particular larval instar and species is present. Once the larvae have left the body, it becomes more difficult to interpret the PMI. Several researchers have explored this aspect, particularly in relation to the rate of change of the larva as it shortens and thickens and subsequently changes its color as the resulting puparium (the pupal case) tans. Up to 24 h after pupariation starts (the period of color change from a white-colored puparium to its final tanned color), it may be possible, under fixed conditions, to estimate the age of the puparia. Thereafter, it may be possible to examine the pupa itself to determine stage of development. However, in both instances further research is necessary on the part of the forensic entomologist conducting the case in order to decide the time period concerned.

The time between the start of the postfeeding stage when the larva starts to wander and the point at which there are metabolic changes triggered by the transition into a puparium remains a problem in terms of estimating the time since death. Work by Charabidze et al. (2008) on the crawling speed of *Protophormia terraenovae* indicated that at 23 °C the maximum speed of movement for a 14-mm larva was 27.8 cm min⁻¹. This calculation allowed the time since the larva had left the body to be determined at this temperature, based upon distance away from the body.

A further limitation in the use of forensic entomology is sparsity of knowledge about life cycles of fly parasites, for example, the parasitic wasp *Nasonia vitripennis* (Walker), a jewel wasp. Parasitoids cause the death of the particular specimen they parasitize. However, with further research, it may be possible to determine the time since parasitization of the colonizer. This could provide a measure of time since death using a different organism and under these circumstances makes parasitoids a useful forensic indicator.

The variation in presence of carrion-inhabiting species in different seasons of the year in countries around the world is also a limitation in their use in forensic entomology. Some insects enter diapause in winter and disappear from view, whilst the distribution of others may vary with season and locality. Further study of insect life cycles and the changes in presence and distribution of species as a result of climate change will help to resolve such limitations and refine the use of insects as proxies for past events.

Analytical Techniques in Forensic Palynology

V M Bryant, Texas A&M University, College Station, TX, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

It is uncertain exactly when the first attempt to use pollen in a forensic application might have occurred. The current information suggests that any attempt made prior to the late 1950s, either failed or was never reported. One of the earliest successful cases using forensic palynology occurred in Austria in 1959 (Erdtman, 1969). Here, pollen was used successfully to link a suspect with the crime scene and the shallow grave containing the murdered victim's body. However, for several decades after that murder case there were no reported attempts to use pollen evidence again in a forensic application. An exception was the collection and analysis of pollen from the holy relic called the Shroud of Turin during the 1970s by Max Frei. In that study, Frei used tape pulls and the trapped pollen on the tapes to attempt to prove the Shroud's origin and authenticity (Bryant, 2000). The next application appears to have been in New Zealand during the early 1980s where pollen was used to solve a case involving the illegal poaching and selling of velvet from deer antlers (Mildenhall, 1990). In the United Kingdom, Wiltshire (1993) first brought attention to the use of pollen in helping to solve criminal cases. As a result of that initial work, the United Kingdom now leads the world in the routine application and use of forensic palynology as part of the armory of forensic techniques available to investigators.

In the United States, there was little interest in forensic palynology until after the events of September 11, 2001, when the twin towers of the World Trade Center in New York City were destroyed by terrorists using commercial airplanes. In an effort to determine who had been responsible for the destruction of the World Trade Center, and where the terrorists may have lived, a number of investigations were begun by U.S. government agencies searching for forensic trace evidence that might help identify the terrorists and prevent similar events in the future. Although none of those federal agencies had ever used pollen or spores as forensic tools prior to 9/11/2001, that event triggered the interest of federal agencies to use palynology (the study of pollen and spores) in their investigations. In the years since 9/11, U.S. federal agencies have relied on palynology to resolve a number of issues including the origin and distribution of illegal drugs, the origin of seized contraband goods, the importation and transshipment of illegal goods, the geolocation of aliens and other items seized or captured at border crossings, the potential link between individual criminals and specific geographical locations, the manufactured origin of weapons and explosive devices, where various vehicles seized during criminal investigations had been driven, the geolocation associated with the use of cell phones and laptop computers, and a wide variety of similar applications involving military, criminal, and civil cases. During these examinations questions are sometimes raised by investigators, and by other forensic specialists about the precision, reliability, and accuracy of using what they often call 'soft scientific data' such as soil profiling and the use of pollen or spore evidence.

Analytical techniques in palynology rely on the identification of pollen and spore types and, in most cases, the ratio of each pollen or spore type to the total palynomorph composition recovered in a sample. Thus, it is often the combined identification of both the pollen taxa and the abundance of each taxon that provide the critical data needed for analytical precision. The primary problem, however, has been that light microscopy (LM) is typically limited to the identification of pollen and spore types either to the family (e.g., Cupressaceae, Poaceae, Chenopodiaceae) or to the generic level (e.g., *Picea*, *Quercus*, *Artemisia*, *Pinus*). Unfortunately, one of the drawbacks of using LM analysis is that it is rarely precise enough to identify pollen confidently to the species level. Sometimes, one must rely upon the higher resolution capacity of a scanning electron microscope (SEM), or a transmission electron microscope (TEM) to establish the precise genus and species of pollen grains found in forensic samples (Milne et al., 2005). Examining entire forensic pollen samples using SEM and/or TEM is time consuming, costly, and requires access to expensive equipment and the expertise of competent palynologists familiar with SEM and TEM usage. Although this can, and has been done (Jones and Bryant, 2007), these techniques are rarely feasible based on the funding constraints facing most investigative agencies.

Discussion

In the United States, attempts to increase the identification precision of pollen and spore evidence in forensic applications have explored various new technologies including computer-based imaging programs designed to identify pollen grains (Allen et al., 2007), examination of the DNA of individual pollen grains, the use of isotope values associated with individual pollen grains, and the potential application of Raman microspectroscopy. To date, these techniques are not commonly used in most palynology applications to forensic evidence because of the limitations associated with each technique. Although these techniques can bring some refinements in the levels of pollen and spore identification, none can yet duplicate the full quantitative range of data achieved by using LM pollen analyses.

Light Microscopy Versus Scanning Electron Microscopy

Jones and Bryant (2007) compared the pollen analysis of a forensic sample using both LM and SEM. In that study, they examined the same sample and conducted a complete pollen analysis using each technique and then identified the advantages and limitations of each. They also discussed a number of considerations that should be examined and considered before

determining which technique to use in any type of forensic analyses of pollen.

Extraction and Processing

Initially one needs to determine whether or not the forensic sample should be examined fresh or chemically prepared for analysis. If it is important to know whether or not some, or all, of the pollen in the sample is 'fresh' and was recently dispersed, then special care must be taken not to destroy that type of evidence by chemically removing the cytoplasm. For example, knowing 'when' pollen was trapped in the keyboard of a laptop computer might be a vital and important clue. Knowing whether the pollen was from fossil types that were recycled or from freshly deposited pollen might aid in identifying the time and use location of the laptop. Similarly, recovering fresh *Cannabis* (marijuana) pollen from the clothing of someone suspected of growing those plants illegally could provide stronger evidence for conviction than the argument that the trapped pollen on the clothing came only from previous dispersed pollen that had been recycled. In another instance, a suspect related to a crime committed in a California avocado orchard could not have been linked to the crime scene had the pollen on his clothing been processed using normal techniques. Avocado pollen is extremely fragile and is easily destroyed using even mild oxidizing methods normally associated with the removal of cellulose and other nonpollen organic debris found in forensic samples.

There are a number of reliable extraction procedures that can be used to prepare forensic pollen samples for both LM and/or SEM analysis (Brown, 2008; Faegri and Iversen, 1989; Moore et al., 1991). The primary objective in most cases is to remove as much debris in the samples as possible, thereby freeing the pollen grains for analysis and preventing remaining debris from obscuring part or all of the individual pollen grains during analysis. Nevertheless, one should make an initial observation of samples before chemical extraction to search for and note what types of 'debris,' such as plant cuticle, coniferous tracheids, phytoliths, starch grains, carbon soot, and similar debris might be present. Those items, when present, can often provide additional clues about the origin of a sample. Next, caution should be exercised in selecting laboratory procedures that will remove unwanted debris but which will also prevent the inadvertent destruction of some or all of the pollen. This is especially critical in pollen samples that come from locations where pollen and spores are already partly degraded or might contain suspected pollen types (e.g., Lauraceae) that are easily destroyed using standard chemical treatments, such as acetolysis (a mixture of sulfuric acid and acetic anhydride). For example, in a pretest of the existing pollen and spore preservation in a series of forensic samples collected from a location with high soil alkalinity, different palynomorph recovery rates were found depending on the extraction process that was selected. In that example, the most successful process consisted of using only 5% KOH, HCl, and HF. When acetolysis or other oxidation procedures were added to the extraction process a portion of the poorly preserved pollen disappeared.

Once a forensic sample has been chemically prepared using appropriate laboratory techniques, the resulting residue can be

added to a suitable mounting media for LM analysis or temporarily placed in a sealed vial containing glacial acetic acid for storage or later use for SEM/TEM analysis. One important consideration for LM analysis is to use a mounting media which will allow the analyst to gently roll or move pollen grains mounted under the coverslip on slides. Often positive identification of individual pollen grains can only be confirmed if critical aperture features, wall construction, and surface ornamentation features can be adequately observed. Often, these criteria cannot always be obtained in only one view of a pollen grain, especially if the grain is partly collapsed, broken, folded, or partly obscured by debris. Thus, it is important that the analyst be able to move the pollen grains and spores into different positions during LM analysis to make positive identifications. One of the preferred mounting media used in forensic palynology is glycerine jelly. Once the pollen sample is mixed with glycerine jelly and allowed to dry under a cover slip on a slide, pollen grains are fixed in their orientation and location. However, placing the tip of a heated implement on the coverslip will briefly melt the media enough to move a pollen grain into a slightly different orientation before the media hardens again. The use of this type of mounting media is essential for many types of situations where pollen grains related to criminal or civil investigations must be repeatedly located on the slides for verification by different palynologists working with the prosecution and/or with defense attorneys. Another alternative, which allows for quicker scanning and counting of pollen grains on slides, is the use of liquid glycerine. Slides made with liquid glycerine can be permanently sealed around the coverslip with clear fingernail polish and the position of pollen grains on those sealed slides will not move provided the slides remain sealed and do not leak, and provided the slides are always stored in a perfectly horizontal position. The location of key pollen grains seen on those slides can be marked using the tip of a fine-point, felt-tip marker. In working on forensic pollen samples where information is critical and is time sensitive, the liquid glycerine technique allows for quicker movement of multiple pollen grains into many different orientations, and also permits the rapid scanning of multiple slides while searching for additional, new pollen taxa. This type of rapid analysis is sometimes needed when individuals are being held temporarily until essential information is determined, often through pollen analysis. Nevertheless, when in doubt of which mounting media to use, and if viewing by multiple palynologists over longer periods of time will be needed, the glycerine jelly technique is preferable.

Forensic samples prepared for SEM analysis must also be processed to remove debris and then rinsed twice with 95% ETOH. Next, one drop of the pollen residue should be pipetted from the ETOH mixture onto a sterile SEM aluminum stub that has been previously coated with an adhesive such as TEMPFIX™. After drying, samples must be coated before using. A common technique is to coat the stub with 400 Å of gold palladium applied in a Hummer II sputter coater. Stubs should be identified by data etched onto the sides or bottom with a diamond pen. One or more marks should also be etched on the top edge of each stub to ensure proper reorientation if a stub is removed. This last point is especially critical for two different types of circumstances. First, if a key pollen grain on a stub must be relocated at a later time to check the identification

or if verification, then the marks on the stub surface will allow for correct reinsertion of the stub in the exact original position (Jones and Bryant, 2007). Second, if a complete pollen analysis using SEM is needed, as has been done on occasions, it is time consuming and often takes a number of hours to complete. Because an SEM pollen analysis cannot always be completed within the time available, one must return several times. One does not want to inadvertently recount the pollen on previously viewed transects. Therefore, one must be able to reinsert the SEM stub in the exact position each time. The markings on the top of the stub enable one to reinsert the stub in the exact original orientation.

Equipment, Cost, Time, and Expertise

In most forensic analytical situations cost is a primary concern. Invariably, the length of time to complete a forensic pollen analysis is also an important factor that must be considered. Other aspects that might determine which technique to use are the availability of equipment and the expertise of the palynologist doing the forensic study.

A good quality light microscope with good photographic capabilities, bright and dark field phase contrast, and differential interference contrast is a costly investment and can range in price from \$25 000 to over \$75 000 (United States). However, once it is purchased, it can be used for years without additional costs other than an annual cleaning, checking alignments, and making needed adjustments. The cost of an adequate SEM, the proper setting with stable flooring to prevent vibrations, cooling systems to prevent overheating, and digital photographic systems can easily exceed \$500 000 (United States); an amount many forensic laboratories cannot afford. There are some less costly SEM 'desktop' versions but often these are not adequate for most forensic studies of pollen grains. Since many forensic facilities cannot afford to purchase and maintain SEM equipment, they must rent beam time from some facility that has available SEM equipment and is willing to rent it to others. The rental cost for beam time will vary greatly and must be considered if one wishes to conduct a SEM study of forensic pollen samples. For identification purposes at both the LM and SEM level, one must be very precise in explaining on what basis pollen types were 'lumped' or 'separated' into various taxa. If time is deemed critical, trying to prepare forensic samples for SEM usage and then examining a pollen sample using SEM technology is generally not a viable option. By far, the fastest and least expensive method of forensic pollen analysis remains the use of LM.

One other problem related to SEM analyses is the expertise of the palynologist. Most palynologists can effectively use a wide variety of LM equipment, but few are well versed on the proper use of SEM equipment. The expertise level of the palynologist may determine which examination technique is used regardless of what method, SEM or LM, might be the most desired or available. Past experience has confirmed that hiring a SEM microscopist to examine and identify pollen in forensic samples is inadequate unless that person is also a trained palynologist (Jones and Bryant, 2007). Skilled SEM technicians are not usually familiar with the range of pollen images they might encounter. Pollen grains and spores in a SEM forensic sample might be partly degraded, folded, collapsed, broken, partly obscured by debris, not exposed in a position that would

enable precise identification, or might be confused as being only a piece of nonpolleniferous debris. Even trained palynologists very familiar with the identity of pollen in LM analyses often find it very difficult to identify many pollen types found in a SEM forensic sample. In the SEM study of forensic samples (Jones and Bryant, 2007) the identity was recorded and each pollen was photographed 'only after both of us agreed on the identification' of each piece of debris or pollen grain. In terms of identifications, there are various levels that are sometimes used by those doing either LM or SEM analyses. For example, it was found that at the LM level one must often be 'lumpers' who include all of the pollen in a genus, such as *Tilia* (linden) or all of the pollen in the family Myrtaceae into a single taxon category because one cannot be certain of significant differences that might reflect separate genera or species. However, if the same sample is examined using the added resolution of the SEM, then often clear distinctions can be seen enabling one to separate different types (species) of pollen, such as in the genus *Tilia* or family Myrtaceae.

LM Pollen Counting and Pollen Identification

Most forensic pollen samples contain debris that needs to be removed to enable pollen grains to be observed. Depending on the type of matrix material in samples, one needs to apply various extraction techniques that could include the use of HCl, HF, KOH, acetolysis, and/or heavy liquid separation. Even under the best extraction circumstances there are often bits of debris remaining in samples when all processing techniques are completed. Debris such as small pieces of lignin, tracheids, phytoliths, charcoal, soot, hair, fungal spores, and mycelia, partly decomposed fragments of cellulose, insect chitin, and tiny silica particles will often remain in processed pollen samples. Sometimes these debris fragments provide additional information about a sample's location, such as soot suggesting an urban location, or abundant fungal spores indicating a location with high fungal activity, or diatoms that indicate an aquatic location. In processed samples, however, these bits of remaining debris can be troublesome and a hindrance to speedy and accurate pollen analyses. For some forensic samples, the presence of fungal spores and hyphae can greatly enhance the final interpretation and when possible should routinely be included in forensic studies (Hawksworth and Wiltshire, 2011). Fungal palynomorphs provide another avenue of trace evidence that is often valuable in assessing the similarity or dissimilarity between samples and is especially important in recognizing specific soils and sediments.

Often, the problems of debris in a sample can be overcome for LM studies by using a mounting media that will enable pollen grains and debris to be moved under the cover slip. Mounting forensic pollen samples in some solid mounting medias, such as Permout™ is not advised because it 'freezes' pollen in one orientation, which may not expose vital clues needed for correct identification. Moving palynomorphs once they are sealed in Permout™ is not always impossible, but it is difficult.

Analysis

The final question is whether or not a completed analysis of a forensic pollen sample will be similar using either SEM or LM.

To test this Jones and Bryant (2007) examined four separate 300 grain pollen counts from the same prepared sample. Two of the counts were conducted using only SEM, and two using only LM, thereby providing 600 grain pollen counts of the same sample for each of the two techniques. After completion of the 600 grain pollen counts, additional material mounted on slides or mounted on SEM stubs were scanned for new pollen types not already seen. These additional LM and SEM scans revealed 20 additional pollen types not found during any of the previous counts. In all, 93 separate pollen taxa were identified in the one forensic sample. The LM counts found 56% of the total 93 taxa and the SEM counts found 79%. Neither method found all 93 pollen taxa. The SEM identification percentage was higher mainly because of the higher resolution level enabling identification of multiple species of individual pollen genera or different genera within families, whereas the LM analysis was limited mostly to the family or genus level of identification. However, ANOVA tests applied to both techniques revealed no significant differences between the relative percentages of pollen taxa in each of the two studies (LM vs. SEM). On the other hand, a T-test applied to both sets of data indicated a significant difference between the LM and SEM in terms of the total number of pollen taxa identified during the analyses.

DNA Analysis of Pollen Grains

To date, the identification and classification of pollen associated with forensic materials have relied mostly on LM analysis. Most plant genera contain many species and each species is often best suited to the specialized environments it occupies. Therefore, if pollen identification to the species level could be improved, it should be possible to add precision to assigning a forensic sample to a specific location or a specific crime scene. Under certain conditions, SEM analyses can provide this type of added precision, but can DNA studies do this even better? DNA analysis of haploid sperm cells, plastids, and mitochondria in the cytoplasm of individual pollen grains has already been accomplished (Longhi et al., 2009). Nevertheless, this suggested application to the study of forensic pollen samples is fraught with problems.

Pollen (the male sex cells) contains haploid DNA which is carried to the ovules of the plant where it then completes fertilization. In angiosperm and gymnosperm pollen grains the cytoplasm contains two or three large vegetative cells that enclose one or two generative haploid cells, plastids, and mitochondria, which means that DNA from the plastids and mitochondria is present in multiple copies (Bennett and Parducci, 2006). DNA amplification from the pollen grain's cytoplasmic sources can then be used to identify the plant species. However, two of the biggest problems facing DNA pollen taxonomic identifications are the limited number of plant species for which DNA sequences are now available (Bennett and Leitch, 2010), and the rapid decay of the DNA contents in dispersed pollen grains.

Extraction and Processing

Extracting pollen from matrix material, such as soils, is relatively easy if you want to do a pollen analysis using LM.

Depending on the number of extraction procedures used and how quickly a sample must be analyzed, a critical forensic pollen sample could be completely processed and an examination begun in as little as 1 h. If time is not critical, and depending on the matrix material to be removed, normal pollen extraction of forensic pollen samples includes a number of processing steps that might take anywhere from about 4 h to several days.

Recovery of individual pollen grains from various types of matrix materials and the subsequent DNA extraction and amplification process is much more complicated and more time consuming than collecting and extracting pollen for subsequent LM analysis (Parducci et al., 2005; Suyama et al., 1996). In one report, a team of scientists recovered and then identified individual pollen grains of one species of *Chenopodium* from a surface soil sample (Zhou et al., 2007). In that study, they collected 10 g of a surface soil, washed it through a sieve with sterilized, deionized water to separate pollen from other debris, and then searched only for one size (species) of *Chenopodium* pollen. Fortunately, the pollen species they used was a small pollen grain enabling the team to screen out both larger and smaller particles of debris before their search began. However, if individual pollen grains in a forensic sample included a wide size range of types, then the minimum size openings of any screening device should be no smaller than about 150 μm , which will remove the larger, but not the smaller debris particles. Right away this makes any potential DNA study of pollen types in a forensic sample much more complicated because of the inability to screen out and remove vast amounts of debris that might fall within the same size range of pollen grains. Assuming that one disregards the problems created by using the larger size screen openings, then the liquid portion of sterilized, deionized water passing through the sieve must be centrifuged in a sterile glass or plastic centrifuge tube and kept sealed to prevent atmospheric contamination. To ensure that all pollen in a sample is collected, the centrifuge should run for about 10 min at a speed of 5000 rpm. Even under those rigid circumstances there is a slight danger of losing some pollen that might never sink (Jones and Bryant, 2004). Next, the sediments should be rinsed in sterilized, deionized water and centrifuged again using the same procedure as before. Analysts conducting these types of studies recommend rinsing samples four additional times using sterile, deionized water (Zhou et al., 2007). When this procedure is completed, small drops of the residue can be placed on a sterile microscope slide for observation. The mounting medium should be additional drops of sterile, deionized water and no cover slips should be used.

Using a compound microscope at magnifications ranging from 100 to 400 $\times$, individual pollen grains can be isolated on the slide and extracted using a sterilized glass capillary tube or a sable hair extraction brush; however, attempting this procedure using a dissecting microscope has proven inadequate (Bryant et al., 1991). Each removed pollen grain should then be transferred to another sterilized slide and carefully rinsed four times using sterilized, deionized water. Using a hanging-drop slide for this procedure is ideal. Great care must be taken to remove the rinse water each time and to ensure that the individual collected pollen grain on each slide is not lost. All extraction and observation procedures must be carried out in a

contamination-free area, such as a clean bench, to ensure no additional pollen grains enter the forensic sample being examined. To ensure the proper care of forensic evidence, all forensic laboratories must comply with standards for cleanliness and should make stringent contamination checks a routine practice.

When the rinsing process is complete and most of the rinse water removed from the slide, the pollen grains should be moved to a clean, flat, glass slide and the location of the pollen grain should be marked and noted using a felt-tip marker. Next, a second sterile glass slide should be gently placed on top of the first slide containing the pollen grain and then gently tapped to crush the pollen grain and permit its cytoplasm to be released. The crushed pollen grain, the exine fragments, and released cytoplasm should then be transferred to a sterile, 0.5 ml Eppendorf tube and suspended in deionized, distilled water. Steps can then be followed to isolate the internal transcribed spacer regions, and then amplify them using a nested polymerase chain reaction (PCR) reaction with two pairs of primers (Zhou et al., 2007).

In a previous successful test of individual pollen grains the researchers found that the resulting sequences produced by PCR reactions were not long enough for positive alignment with known DNA sequences in established plant DNA databases. Therefore, the researchers had to take the purified pollen DNA and clone it into a pGEM-T easy vector (Promega) and then transform it into cells of *Escherichia coli* (Zhou et al., 2007).

Equipment, Cost, Time, and Expertise

To conduct DNA analyses of equivalent forensic pollen samples one must have access to special equipment designed for the extraction, amplification, and recovery of DNA fragments needed to make positive identifications. Of even greater concern in most DNA forensic pollen studies is having an available DNA database of plant species against which amplified samples can be matched.

The original Plant DNA C-values Database is a comprehensive catalog listing the nuclear DNA content, or in diploids the genome size, for a small number of land plants and algae. Dr. Michael D. Bennett and Dr. Ilia J. Leitch of the Royal Botanic Gardens, Kew, England, created the original database, which has been continuously updated and now contains C-values for 7058 species. Of these, 6287 species are from angiosperms, 204 gymnosperms, 82 pteridophytes, 232 bryophytes, and 253 algae. By comparison there are about 352 000 angiosperm species, 1050 gymnosperms, 15 000 pteridophytes, and 22 750 bryophytes (Bennett and Leitch, 2010). Therefore, the current known DNA database for plants is very limited and contains only 0.18% of the total, which may not include critical DNA information about many pollen species isolated from some forensic samples. An added problem is that among the known plant types with DNA profiles, the pollen of some species can hybridize easily with other species of the same genus producing an F1 generation with DNA that is not identical to either parent (Schaal et al., 1998; Valbuena-Carabana et al., 2005).

Pollen Counting and Identification

Pollen analysis (quantification of taxa and rapid identification) for a typical forensic sample can often be accomplished

fairly quickly. For DNA pollen studies, similar levels of precision and rapid analysis of individual samples are impossible to obtain using current technology. The procedures needed to recover each pollen grain, prepare each pollen grain for DNA analysis, and then attempt to amplify the recovered DNA fragments so they can be matched against an available plant DNA database are far too time consuming and costly to even be considered for most forensic work. What is even more problematic is that pollen grains, which have lost their cytoplasm for a variety of reasons, will not produce any DNA fragments needed for amplification (Bennett and Parducci, 2006). This means that one might have to isolate a large number of individual grains from a single forensic pollen sample in hopes of finding a few that still contain sufficient cytoplasm for DNA amplification. For those successful few containing DNA, the final problem focuses on the hope that the recovered DNA fragments can then be matched to an available DNA database.

A significant problem of DNA identification studies, as it might be applied to any forensic pollen sample, is the inability to determine the quantitative relationship of each pollen type to all other taxa present. Even if successful, DNA identification studies of any pollen sample could only provide a ubiquity view of the sample. What the resulting DNA data cannot provide is information about how abundant or scarce each pollen type might be in a total sample.

Analysis

The analysis of most forensic pollen samples relies on the identification of individual pollen types, and on the quantitative relationship of each pollen type to all other types encountered in the same sample. A specific forensic sample might contain pine, spruce, grass, and sagebrush pollen grains; but it might be equally important to know whether or not those taxa are represented by a single pollen grain or by a large percentage of the total pollen count within the sample. A single pollen grain from any of those types might reflect nothing more than an unusual case of long distance transport of an airborne pollen grain (Faegri and Iversen, 1989) or possible contamination. However, if a forensic sample contains 5, 10%, or more pollen for any taxon, then that provides significant information about the probable location of the sample or its similarity or dissimilarity to other samples collected from either a crime scene or a possible suspect. A pollen analysis using LM can provide essential quantitative information about each pollen type but a DNA study provides only ubiquity data as to the presence/absence of taxa without any additional quantitative information.

Finally, aside from the other already mentioned limitations created by the data obtained from the DNA of individual pollen grains, the ultimate cost and time needed for these types of studies make them unsuitable for forensic pollen analyses. In one nonforensic related study, which attempted to recover and identify individual pollen grains in a surface soil sample, the researchers found that they could only derive DNA data through amplification of 40% of the total number of pollen grains they isolated and then tested (Zhou et al., 2007). This means that 60% of all the pollen grains that were individually isolated and then tested for DNA amplification proved useless. Any effort where even a small portion of a

sample's pollen is unavailable for analysis does not provide the type of reliability needed for the precision necessary in forensic applications.

Perhaps in the future as new and better techniques are developed for the recovery and amplification of DNA in individual pollen grains, this type of analysis technique might become useful. Nevertheless, even with better techniques of recovery and amplification, DNA studies of pollen grains will still have many limitations because it provides only presence/absence data and it can be used only on pollen types still containing cytoplasm rather than all the pollen present in a forensic sample.

Raman Spectroscopy of Pollen Grains

The concept and use of Raman spectroscopy was named after its discoverer, the Indian scientist Sir C. V. Raman, who observed the Raman Effect of sunlight in 1928 and was recognized for his discovery with a Nobel Prize in Physics in 1930. In Raman spectroscopy, a laser beam is used to excite electron transitions in the molecules of a sample. After excitation, the majority of the electrons return to the ground state by releasing photons of the identical wavelength as that of the laser beam they absorbed. However, a small percentage of the excited electrons in a sample undergo Raman scattering, releasing scattered light of different wavelengths prior to relaxing to the ground state. As a result of the scattering, less energy is emitted in the transition back to ground state than was originally absorbed in the excitation. The difference in these two energies is referred to as the Raman shift. Since various molecular bonds within a molecule undergo Raman shifting of different wavelengths, the unique Raman spectra or patterns of shifts, as a function of wavelength, can be used to identify the molecular composition of samples. Because pollen from different taxa contain different molecular compositions, Raman spectroscopy should prove beneficial in separating various pollen types by family, genus, and even species (Atanu et al., 2005).

Raman spectroscopy has gained a great deal of attention for its use in forensics as an analytical tool. There are a number of advantages of Raman spectroscopy, which makes it ideal for applications in the field of forensics. First, the field of Raman spectroscopy is rapidly changing as improved techniques broaden its potential uses. Second, Raman spectroscopy is a noncontact and nondestructive technique, which means that many types of items and samples of forensic trace evidence do not have to be destroyed or changed in order to enable analysis. Third, Raman spectroscopy does not require any special type of sample preparation prior to examination and analysis. This means that trace evidence can often be examined first using Raman spectroscopy, and then used for other types of analyses, which might need to alter or destroy the material during analysis (such as pollen extraction techniques). Fourth, only minimal amounts of material are required for a complete analysis; sometimes even microscopic amounts of trace evidence can be examined. Fifth, Raman spectroscopy is highly sensitive to slight differences in the molecular and chemical composition of materials, which enables it to detect very small differences in samples. That type of high resolution potential can be essential in the study of forensic samples where minor

differences are essential to distinguish one type of paint from all others, one type of glass from other types, or linking some synthetic fiber to a unique production time at only one manufacturing facility.

Extraction and Processing

One problem in using this technique on pollen grains is that the spectral signatures of carotenoid pigments embedded in the surface and exine of pollen grains can provide signals leading to the misclassification of pollen grains; therefore, those carotenoid signatures should be eliminated prior to using Raman spectroscopy. A common method of removing the carotenoid signals is to photo-destroy the carotenoids using a 633 nm laser light prior to attempting the Raman spectral analysis.

Schulte et al. (2009) suggest that signatures of the carotenoid pigments might provide valuable information that could be used as an additional method to distinguish one pollen species from another. They suggest that it is important to first take a Raman spectrum signature of a pollen grain, then photo-destroy the carotenoids, then take a second Raman spectrum signature. By using the comparisons of the two spectra it would be possible to isolate and catalog the different spectral features of carotenoid pigments in each pollen type examined.

Equipment, Cost, Time, and Expertise

The cost for equipment to conduct Raman spectroscopy varies depending on the type of desired studies. There are three basic types of Raman instruments: bench top spectrometers, fiber optic spectrometers, and Raman microscopes. For pollen studies one would need a Raman microscope.

The time needed to conduct Raman spectroscopy analyses depends on the level of resolution needed, whether or not the carotenoid pigments in the pollen wall and surface need to be removed, and how many pollen grains in a sample need to be examined. Another time-consuming requirement would be determining each of the precise X and Y coordinates (locations of the pollen grains within the matrix materials) in each sample where the Raman laser beam and analysis must be focused. Once pollen data are collected using Raman spectroscopy, then those data must be compared against a previously recorded pollen database of the spectral parameters for each pollen taxon. This becomes a major problem because at present there are very few pollen taxa for which any type of Raman spectral data are known.

Conducting and interpreting the signatures of Raman spectroscopy require a special expertise, which most palynologists may not have. Therefore, these types of analyses would require either a palynologist to work closely with someone familiar with Raman spectroscopy, or it would require the palynologist to learn how to use and interpret the results of Raman spectra produced by Raman spectroscopy.

Pollen Counting and Identification

When trying to identify pollen grains to species using Raman spectroscopy, an important question is whether individual variations in pollen grains reflect different species of the same

genus, or are there expected differences found within pollen signatures of the same species. Ivleva et al. (2005) found that to answer that question required them to examine high resolution spectral maps produced from five to ten individual pollen grains per species. They reported that developing a single high-resolution spectral map of a single pollen grain requires about 72 h. To obtain the five to ten high-resolution spectral maps needed per pollen species, a researcher would need to spend an estimated 360–720 h gathering data for each pollen species being considered. Once completed, the five to ten spectral maps for a pollen species can then be averaged to provide the expected spectral variations expected within the Raman signatures of one pollen species. However, before those individual pollen grain signatures can be obtained or recorded, a researcher must first destroy the spectra produced by the carotenoid pigments in that pollen grain species by using a pretreatment of 633 nm laser light. Failure to do this would obscure the true Raman spectral signatures of each individual pollen species.

Another problem with Raman spectroscopy is linking spectral signatures to individual pollen species. A major problem can be created because of the spheroid, triangular, or oblong shape of most pollen grains, because of the complex variety of surface ornamentations, and because of aperture variation and numbers. These types of variations create a heterogeneous pollen surface area with slightly different molecular signatures depending on where on the pollen grain the Raman laser beam is focused. This means that the focal position and the resulting spectral information of the excitation laser can vary depending on where on the pollen grain surface and which potential ornamentation feature is being examined. Additional problems are created by the pollen exine, which can vary in thickness depending on whether there is an aperture, fissure, or operculum. Some pollen grains have a thin exine while others have a thick or a multilayered exine. Different spectral signatures will be recorded depending on which exine surface is being examined and how deep into the exine the laser beam is focused.

Analysis

The most important question is whether or not Raman spectroscopy can be effectively used in forensic samples to determine the precise pollen species present. Ivleva et al. (2005) note that for many types of pollen the precise species and genus level identification should be possible using Raman spectroscopy, provided one is able to generate the needed signature patterns for each potential pollen type that is expected to occur in a forensic sample. If it requires 360–720 h to gather the data needed to create a reference for each pollen species, and if two or three dozen potential pollen types might be expected in a specific forensic sample, it would take weeks of preparation time obtaining the needed signatures before one could even begin the study of the forensic sample. Furthermore, any unknown signature might reflect some pollen type, which was not expected and therefore, would have no comparative reference signature. One advantage is that often pollen grains belonging to different species of the same genus will have spectral signatures that are similar enough to place all species into the same genus. Likewise, the spectral signatures of

many genera within the same plant family also have signatures that are similar enough to identify them with that family (Sengupta et al., 2005). In both types of spectral signatures, some studies suggest the patterns are similar enough to recognize they are related, but different enough so that individual species and genera can still be identified provided sufficient reference signatures were available for comparison. Yet another problem is that preliminary studies have noted that in some plant taxa there are essentially no differences among similar species in a single genus. Among the oaks, for example, researchers have been unable to identify spectral signatures that are unique to only one species in the genus *Quercus*. This inability is believed to be caused by the frequent hybridization among different species of oaks (Valbuena-Carabana et al., 2005). Although not yet tested for a number of other plant genera, similar types of hybridization are known to occur in many plants and thus, it could present similar problems of signature resolution.

Although a few studies have shown that successful spectral signatures can be used to identify certain types of pollen using Raman spectroscopy (Manoharan et al., 1991), the use of this technology is currently hindered by a number of problems. First, very few pollen grain spectral signatures are available for comparison use. Second, establishing more pollen spectral signatures requires a very large investment of time and effort for each taxon. Therefore, the question remains as to what organization could provide the funding needed to conduct even a single forensic pollen study using this type of technology. Third, similar to the problems of using DNA studies of individual pollen grains in forensic samples, current techniques using Raman spectroscopy do not offer quantitative information about the abundance or rarity of each pollen type in a sample. Raman spectroscopy, similar to DNA, provides only ubiquity information rather than the quantitative data related to each pollen taxon; which is usually considered essential in most forensic pollen studies. Finally, in a study conducted by the author with a few colleagues it was experimented to see if Raman spectroscopy could be used to distinguish the differences between fresh *Celtis* (hackberry) and fresh *Cannabis* (hemp, marijuana) pollen. After mounting the grains from both types it was noted that some of the pollen grains in each group were folded, deflated, broken, or overlapped with other grains or with debris. When setting the laser beam on specific targets within each group it was found that the resulting data was not conclusive enough to provide with certainty the identity of the pollen taxon being examined. In other words, the ranges of variations were too great and somewhat overlapping between both groups. It was suspected that the problem may have resulted from the laser beam reading the surfaces on some grains, the interior of the exine on other grains, the aperture on other grains, and the surface morphology on still others. It is possible that perhaps some of the returning signatures came from a focus in the interior of some grains that may have been folded.

Stable Isotope Analysis of Pollen Grains

The application of stable isotope analysis to various materials has been growing in importance since the early 1970s and its

use has expanded widely. Today, stable isotope analysis is a useful technique applied to a number of disciplines including forensics, archaeology, paleoenvironmental studies, and questions related to geolocation. The principle behind isotope ratios is that organic and inorganic materials retain a record in their molecules of information generated from their immediate surroundings (Hurley et al., 2010; West et al., 2006).

Thousands or millions of years later, even if the original materials move or are buried, those initial environmental isotope signals can be used to identify the environment and the general geographical location where an item originated. Other types of important data generated from stable isotope analyses focus on direct inferences regarding human and other animal diets, nutritional levels, and subsistence patterns (Bousman and Quigg, 2006). In archaeology, for example, isotopic signatures are used to gain insights into prehistoric diets, human migration patterns, trade routes, class status in burials, and the environmental conditions that confronted ancient cultures (Calo and Cortés, 2009).

Although there have been many studies of the stable isotopes found in plant leaves, wood, stems, and roots, it has only been during the last decade that scientists have begun to focus on the use of isotopes recoverable from types of cellulose, lignin, *n*-alkanes, *n*-alkenoic acids, phenylglucosazone, and other materials, including individual fossil pollen grains. The resulting data serve as proxy information for determining paleoenvironmental conditions and climatic variations (Jahren, 2004). Because stable isotopes of pollen grains from different genera and species of plants also carry different signatures, isotope analyses have the potential for providing additional information helpful in identifying pollen types (Descolas-Gros and Schölzel, 2007). Under the right conditions where information from some sample might be deemed critical, isotope studies of pollen grains might provide a complementary technique that could be combined with standard pollen analyses in a forensic study. Nevertheless, trying to conduct such a study would be costly, time consuming, and complicated.

Extraction and Processing

An initial problem in conducting stable isotope studies of pollen is to isolate the pollen grains from the surrounding matrix. Under many circumstances, one might consider using a pollen extraction technique such as acetolysis to remove unwanted organic debris and attempt to concentrate the pollen grains (Faegri and Iversen, 1989). However, as Amundson et al. (1997) and also Loader and Hemming (2000, 2001) point out, the use of the acetolysis treatment will alter the carbon isotope composition in the pollen wall thereby providing inaccurate signals. Other extraction techniques, which have been suggested for use in concentrating pollen for isotope analysis, include the use of Schulze's solution and/or the use of concentrated sulfuric acid. Jahren (2004) found that the sulfuric acid extraction technique has less of an effect on the composition of the pollen wall and appears to do less damage to the isotope composition ratios. In his study, he found that the sulfuric acid extraction technique altered the carbon isotope composition ratios of grass pollen by 2.5%, whereas using the acetolysis treatment altered the composition of the same pollen type by

as much as 5%. However, both techniques significantly alter the original carbon isotope ratios of pollen grains and thus neither is suitable.

A major problem conducting isotope studies of individual pollen grains in various types of samples is that the use of almost any chemical treatment designed to concentrate the pollen and remove nonpollen debris in samples will alter the molecular composition of the pollen wall. Concentrating pollen in samples, removing debris, and then finding individual pollen grains of each specific taxon is very labor intensive and expensive. Jahren (2004) reports that it was necessary to manually isolate up to 2500 individual pollen grains of a single species in order to recover sufficient pollen for using automated combustion methods to identify the isotopes of that pollen species. However, Loader and Hemming (2004) state they achieved these same results for a $\delta^{13}\text{C}$ analysis with as few as 350 spruce pollen grains in one sample. Even at that reduced level, these techniques are very labor intensive and could never be used for a forensic sample that might contain small numbers of pollen grains.

Recently, Nelson et al. (2008) reported that it was no longer necessary to isolate hundreds or thousands of pollen grains to conduct stable isotope analyses of pollen. They demonstrated that they can analyze the stable isotopes of individual pollen grains using a spooling-wire microcombustion device interfaced with an isotope-ratio mass spectrometer. Using this technique, they isolated pollen grains that were initially obtained from a small deposit of sediment. First, they used nano-pure water to produce a thin slurry of the sediment that was then transferred to clean microscope slides with additional nano-pure water. The slurry was gently washed on the slide with additional nano-pure water until individual pollen grains could be located at $200\times$. Individually, each grain was identified, isolated, and then carefully removed and analyzed for $\delta^{13}\text{C}$ (Nelson et al., 2008).

Equipment, Cost, Time, and Expertise

Palynologists are usually not trained in stable isotope analysis, nor do most palynology laboratories have the equipment needed to conduct isotope analyses. The role the palynologist might be able to play in these studies would be to identify and collect samples from forensic sources, use appropriate techniques to isolate, concentrate, identify, and then remove individual pollen grains for analysis by those trained in isotope analyses.

Pollen Counting and Identification

The pollen collecting and identification would need to be done by a trained palynologist. The number of taxa to examine and the number of pollen grains to collect would depend on time, funding, and the expected goal of the project. Even in circumstances where this type of isotope study was attempted, the following analysis and interpretation phases would be even more complicated.

Analysis

During photosynthesis, the carbon isotope intake and later the formation of plant tissues, including the pollen wall, will be

influenced by the environment. Oxygen and hydrogen atoms from leaf water are incorporated into the initial products of photosynthesis and then form a component of the oxygen and hydrogen of other plant compounds. Therefore, studies of stable isotope ratios in plant material have the potential to reveal information about the parent plant's geolocation and environment. During plant formation and growth $\delta^{13}\text{C}$ ratios record the environmental benefits or restraints on photosynthesis, nitrogen isotope ratios ($\delta^{15}\text{N}$) record the nitrogen fixation, and the isotope ratios of hydrogen ($\delta^2\text{H}$) and oxygen ($\delta^{18}\text{O}$) record precipitation and water availability (West et al., 2006). Because of the variety of stable isotope ratios found in plant materials, including pollen, these materials have the potential to reveal important information about the parent plant's location and environment, which might prove especially useful in trying to find the origin of seized illegal drugs (West et al., 2009a,b).

Loader and Hemming (2004) examined the oxygen ($\delta^{18}\text{O}$) and hydrogen (δD) isotope ratios in pollen grains and suggested that these ratios could be used to predict precipitation availability at the time of pollen grains were formed. They also found, during an earlier study, that there was a positive relationship between $\delta^{13}\text{C}$ signatures in the exine of pollen and the climatic temperature of the environment when the pollen-producing plant lived (Loader and Hemming, 2001). As these two researchers found, there seems to be a close correlation between the individual stable isotope ratios found within a single plant's leaves, wood, stems, and roots. They also suggest that this may be true for the exine of the pollen a plant produces. If further testing reveals these aspects to be true, then it means that many of the stable isotope ratios already developed for other tissues in many plant species can also be used as a database for isotope ratios in pollen (Jahren, 2004).

Nelson et al. (2008) examined isotopic ratios from grass pollen collected from a series of lakes to determine if lake-deposited pollen reflected the surrounding grassland environment. Their study focused on two important aspects. First, they wanted to determine if individual grass pollen grains, deposited in nearby lake sediments, could serve as a proxy for the host grass communities (either C_3 or C_4) from which they originated. To test this, they collected surface sediments from the bottom of ten different lakes surrounded by areas dominated by either C_3 or C_4 grass communities. Next, they tested individual pollen grains collected from the top sediment layers at the bottom of the ten lakes against fresh grass pollen grains collected from grasses growing in areas around each of the lakes. Their testing confirmed a strong $\delta^{13}\text{C}$ signature correlation between the individual grass pollen grains deposited in the lake sediments and the surrounding C_3 or C_4 grass community. Second, they confirmed that the examination of individual grass pollen grains provided distinct advantages over studies of the isotopes from bulk sediment samples collected at the bottom of the same lakes. They found that the bulk samples most frequently reflected the aquatic plant habitat rather than the surrounding terrestrial grasses.

The future use of information derived from stable isotope studies for pollen grains associated with forensic applications is questionable because there are a number of problems and limitations. First, more work is needed and confirmation of the relationship between the various environmental constraints

and the stable isotope ratios in pollen grains is essential. Second, one needs to determine if individual pollen genera and even species can be recognized by some unique combination of isotope ratios in the pollen walls, or will continued studies show that isotopes of pollen grains are important only because they offer clues about the environmental surroundings and perhaps their geographical origins. Third, it is already known that the time and especially the costs of trying to isolate individual pollen grains in a forensic sample and then carrying out the isotope studies on each pollen grain can become very expensive. Fourth, in any given forensic sample all of the pollen may not have come from plants in only one location; therefore, the isotope signatures of a suite of pollen in a single sample might generate a variety of interpretations with no verification as to which ones might be the most important. Fifth, similar to some of the other new analytical techniques mentioned, isotope studies are potentially limited to providing ubiquity rather than quantitative studies of individual samples.

Summary

Forensic studies using pollen as trace evidence are in their infancy in terms of usage and acceptance worldwide. In some countries, the use of forensic palynology has become routinely accepted and its use has become court tested while in other countries neither is occurring at present. The United Kingdom is the recognized world leader in the use of forensic palynology yet prior to the 1990s it was virtually unknown in that country. It was not until Wiltshire (2003) began her extensive forensic pollen work and encouraged law enforcement agencies to consider pollen studies in a wide range of criminal cases that it became a routine type of forensic trace evidence in the United Kingdom. In New Zealand, the early work by Mildenhall (1990) issued in the use of this technique in that country. In Australia, the application of pollen studies, as it relates to forensic cases, was little recognized and appreciated until Bruce and Dettmann (1996) published an article pointing out the potentials for its use in that country. Later, Milne (2005) conducted what may be the earliest application of the use of forensic palynology in Australia. In Canada, Mathewes (2006) reported that aside from a single case where pollen evidence was a factor in a 1987–97 era civil lawsuit between the national government and Native American Canadians, there has been little use of this technique in Canada. Similar to Canada, there has been little effort or wide spread appreciation for the use of pollen as trace evidence in forensic applications within the United States (Bryant and Jones, 2006).

Since the beginning of the twenty-first century, the world has become a more dangerous place to live. Today, rapid travel and instant communication across continents, coupled with the worldwide rise in local and regional conflicts as well as crimes associated with the illegal manufacture and use of drugs have created many unsafe regions for travel. Piracy on the high seas combined with acts of international terrorism has placed a high premium on the safety of military and civilian personnel. One effective way to deal with these growing problems is to find new and more effective ways to outwit criminals and catch terrorists before they can commit acts of mass destruction, such as the 2001 bombing of the World Trade Center in New York

City or the 2005 bombings that occurred in the London Underground and also in one of its double-decker buses.

Although there is no 'magic bullet' that will solve all of these problems, the wider use of forensic palynology might help identify and prevent the wider spread of criminal activity and terrorism. The analytical techniques discussed in this article need more development and refinements before they will be of much value as tools in forensic palynology. Nevertheless, with possible future technological developments in examining pollen using DNA, Raman spectroscopy, and stable isotope analysis, and with the hope for a reduction in costs, these techniques may play a wider role in forensic palynology. Likewise, the increased applications of SEM and TEM may be feasible in the future provided costs and time can be reduced. For the present, however, the most reliable and least expensive analysis technique in forensic palynology remains the use of a light microscope by a highly trained palynologist.

New technology is important, but there remains no shortcut for quick results without the adequate and careful training of competent forensic palynologists. In other areas of forensic sampling, examples have been seen of how doubt and suspicion are easily raised when those charged with examining forensic evidence are found to be guilty of using hasty or improper techniques (Fisher, 2008). Because forensic palynology is still a relatively new technology it has rarely been victimized by those doing incompetent or inaccurate analyses, and hopefully, with international efforts, it might remain that way. What is most needed is wider appreciation for the potential results that this discipline can offer.

Acknowledgments

I wish to thank Drs. Sarah Brooks, Gretchen Jones, and Jason West for their review of portions of this article and for their helpful suggestions.

U-Series Dating

W G Thompson, Woods Hole Oceanographic Institution, Woods Hole, MA, USA

© 2013 Elsevier B.V. All rights reserved.

Introduction

The known decay rate of natural uranium into a series of daughter isotopes provides a radiometric clock that is one of the very few methods for dating natural materials over the last 600 000 years. U–Th dating of carbonates is one of the most accurate and precise methods in geochronology and is the key chronometer for the Quaternary. U-series geochronology has been applied to the dating of climate records in speleothems (cave deposits), the calibration of the radiocarbon timescale, and the reconstruction of sea level from fossil corals. The dating of fossil corals that once grew near the sea surface is one of the premier methods for reconstructing sea level history. Over the last 30 years, technical advancements in analytical capabilities have led to continued and significant improvements in dating precision (Stirling and Andersen, 2009). In addition, better understanding of U-series systematics in corals is leading to more accurate ages (Thompson, submitted). In principle, any material that contains a sufficient amount of uranium that is not in radioactive equilibrium with its daughters is suitable for dating. U-series dating has been applied to a wide variety of materials including volcanic rocks, marine sediments, bone, teeth, mollusks, cave deposits, reef-building corals, and deep-sea corals. The dating of each of these materials has had its successes and difficulties that are documented in a recent and detailed review of U-series geochemistry (Bourdon et al., 2003). In particular, reef coral and speleothem dating has been of crucial importance for calibrating the radiocarbon timescale, establishing sea level variability, testing orbital theories of climate change, and resolving details of Quaternary climate change over a broad range of timescales.

There are three U-series decay chains that start with the naturally occurring radioactive isotopes ^{238}U , ^{235}U , and ^{232}Th and end with stable isotopes of lead: ^{206}Pb , ^{207}Pb , and ^{208}Pb , respectively. While each decay chain includes a dozen or more isotopes, the most widely used U-series isotopes for Quaternary dating are the first two products in the ^{238}U decay chain: ^{234}U and ^{230}Th . In the ^{235}U decay chain, the ^{235}U and ^{231}Pa parent–daughter isotope pair has also been used in recent years. Both ^{238}U and ^{235}U are long-lived isotopes with half-lives of 4.47 and 0.7 billion years, respectively, while the half-lives of their immediate daughters are much shorter: 245 thousand years (ka) for ^{234}U , 76 ka for ^{230}Th , and 33 ka for ^{231}Pa . This large difference between parent and daughter half-lives has an important impact on these U-series systems. Over Quaternary timescales, the change in the parent's activity, or number of decays per unit time, will be negligible, and the activity of the daughter isotope will change until the number of atoms supplied by the decay of the parent equals the number of atoms removed by decay of the daughter. This condition is known as radioactive or secular equilibrium and is characterized by equal activities of parent and daughter or a parent–daughter activity ratio of 1. Because the change in ^{238}U

or ^{235}U activity is negligible on these timescales, the return of a system to secular equilibrium is controlled by the change in daughter activity and therefore its half-life. Left undisturbed, parent–daughter pairs will attain equilibrium in about six half-lives of the daughter isotope.

A U-series system in radioactive equilibrium cannot be used as a chronometer, but dating rather requires an initial state of disequilibrium. Therefore, U-series dating is sometimes referred to as disequilibrium dating. U-series dating is anchored in a few fundamental principles (Edwards et al., 1986). Many carbonates precipitated from natural waters contain significant amounts of uranium and negligible levels of thorium. This is ideal material for U–Th dating, which is based on the ingrowth of ^{230}Th . Uranium is commonly fractionated from its immediate daughters in natural waters due to their contrasting geochemical properties. In the presence of oxygen, the solubility of uranium in natural waters is fairly high, while the solubilities of Th and Pa are quite low. Furthermore, both Th and Pa have a strong tendency to adsorb onto particles and be removed from solution. Therefore, both abiotic and biogenic carbonates precipitated from natural waters frequently contain significant uranium and negligible thorium and protactinium concentrations, an ideal situation for U-series dating. The dating of corals and speleothems has been quite important for establishing Quaternary chronologies as well as for reconstructing sea level and climate change histories, and the dating of these materials provides an instructive illustration of U-series geochronology.

Dating of Reef Corals

The dating of reef corals has been instrumental in extending the radiocarbon calibration past the limits of tree rings and has been used to reconstruct the changing sea levels of the Quaternary (e.g., Thompson and Goldstein, 2005). The most unambiguous record of sea level comes from fossil reef corals, which grow near the sea surface. In principle, it should be possible to date corals extremely accurately by the decay of natural uranium that is incorporated into the coral skeleton during growth (Edwards et al., 1986). In practice, much U/Th coral dating is complicated by significant open-system behavior of U-series nuclides in corals. The aragonitic skeletons of corals initially contain several ppm of uranium and negligible amounts of Pa and Th and are therefore ideal candidates for U-series dating providing the system remains closed. Unfortunately, the delicate and porous structure of corals leaves them susceptible to postdepositional alteration that can seriously degrade the accuracy of U/Th ages. Gross forms of alteration such as partial dissolution, recrystallization, secondary cements, and significant uranium or thorium loss or gain are readily detected by routine screening procedures. However, a more subtle process commonly affects the ages of fossil corals

that appear to be otherwise pristine. Living corals accurately record the uranium isotopic composition of modern seawater (Robinson et al., 2004). However, it has long been known that uranium isotope ratios of most older fossil corals have more ^{234}U than can be explained by closed-system decay from initial seawater uranium. Furthermore, it has been demonstrated repeatedly that corals with excess ^{234}U have excess ^{230}Th and, therefore, older U-series ages (Bender et al., 1979; Gallup et al., 1994; Thompson et al., 2003). These open-system effects are best documented in corals older than 40 ka that have been uplifted into terrestrial environments by tectonic processes (Figures 1 and 2). It is not entirely clear at this time whether U-series ages of younger corals are similarly affected. However, these corals would be expected to have very subtle shifts in their isotope ratios that might be difficult to detect. Older marine aragonite sediments show patterns of open-system behavior that are very similar to older uplifted corals (Henderson et al., 2001), suggesting that the process disturbing U-series nuclides in corals is not restricted to terrestrial environments.

As it became obvious that many older corals showed significant signs of open-system behavior, dating efforts focused on identifying those few corals that satisfied the closed-system requirements of conventional U/Th dating. The most widely used and sensitive test for open-system behavior is the initial

Figure 1 A U/Th activity ratio diagram illustrating the major processes affecting U-series dating of older corals. Closed-system compositions for 95–130 ka corals are expected to lie along the arc near the bottom left of the diagram. The coupled adsorption of ^{234}Th and ^{230}Th produced by radioactive decay of uranium in the reef matrix will produce a linear array of isotopic compositions as indicated. The gain and loss of uranium or thorium will move compositions to the left or right if the isotopic composition of the added uranium is similar to that of the coral. Data are isotopic compositions of corals from the Barbados MIS 5c terrace. Reproduced from Thompson WG (submitted). Why the duration of the Last Interglacial is systematically overestimated. *Earth and Planetary Science Letters*.

$^{234}\text{U}/^{238}\text{U}$ ratio, which can be calculated from a coral's measured $^{234}\text{U}/^{238}\text{U}$ ratio and the U-series age. While criteria vary somewhat among investigators, there is an established consensus that for 'reliable' ages, corals should have initial $^{234}\text{U}/^{238}\text{U}$ ratios within some small range of that expected from the closed-system decay of a modern seawater uranium isotope ratio (e.g., Gallup et al., 1994). However, recent modeling of diagenetic processes suggests that such screening only removes the most egregious age artifacts, without removing a strong and systematic bias toward artificially older ages (Thompson, submitted). Investigators have also tried measuring isotopes of a second U-series chain, $^{231}\text{Pa}/^{235}\text{U}$, as an additional check for closed-system conditions (e.g., Gallup et al., 2002). The agreement of U/Th and U/Pa ages, commonly illustrated on a concordia diagram, is taken as evidence of a closed system. Cheng et al. provide a full discussion of the combined U/Th/Pa system (Cheng et al., 1998). If both initial $^{234}\text{U}/^{238}\text{U}$ and Th/Pa concordance criteria are used, only a few percent of all coral ages measured are considered 'reliable.'

Corrections to U-Series Coral Ages

As the empirical relationship between $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ or conventional U-series age in older corals became clearer, models were developed to quantify this relationship and correct conventional ages for open-system effects. Although continuing improvements in measurement techniques are desirable and important (Andersen et al., 2004; Potter et al., 2005), it has been clear for some time that the accurate dating of older corals is limited primarily by a lack of understanding of their U-series geochemistry rather than the precision of measurement techniques (Bard et al., 1991; Chen et al., 1991; Hamelin et al., 1991).

The strong positive correlation between excess ^{234}U and older conventional ages in corals was discovered early (Bender et al., 1979), has been confirmed repeatedly (Gallup et al., 1994; Stirling et al., 1998, 2001; Thompson et al., 2003), and has been generally accepted as a screening criteria for almost 20 years (Gallup et al., 1994). This correlation between $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ ratios for corals from the same terrace demonstrates that corals have experienced the addition of these isotopes in a systematic manner (Gallup et al., 1994). Until very recently, this association of ^{234}U and ^{230}Th seemed to be impossible to explain with any geochemically reasonable scenario, due to the strongly contrasting behavior of uranium and thorium in natural waters. The earliest isotope addition model was based on the empirical correlation of $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{238}\text{U}$ in corals of approximately the same age (Gallup et al., 1994). A constant addition of ^{234}U and ^{230}Th over time was assumed and used to calculate 'addition lines' that approximated empirical trends. This model was used to establish a criterion for an 'acceptable' range of initial $^{234}\text{U}/^{238}\text{U}$ rather than to correct coral ages for the observed isotope addition.

Shortly thereafter, it was proposed that the isotopic anomalies observed in corals are best explained by the alpha-recoil mobilization during radioactive decay of ^{230}Th and ^{234}Th (which quickly decays to ^{234}U ; Fruijtier et al., 2000). At the same time, it was demonstrated that this process could explain

Figure 2 Examples of diagenetic impacts on coral ages. (a) The effects of coupled ^{234}Th and ^{230}Th addition: These 11 subsamples of a large individual coral from the Last Interglacial terrace in Western Australia must all be the same age. However, the ages range from 122 to 136 ka, encompassing the entire range of ages commonly reported for the Last Interglacial. All but one of the samples fall along the theoretically predicted trend for coupled ^{234}Th and ^{230}Th addition, demonstrating that this is the dominant process producing the age artifacts in this coral. The single sample that plots off the addition line has lower ^{238}U and higher ^{232}Th than the others. (b) The effect of uranium addition: Ages and initial $\delta^{234}\text{U}$ for two corals (four subsamples each) from the Last Interglacial terrace in the Yucatan. The vertical lines show the upper limits for 'reliable' (155) and 'strictly reliable' (151) ages according to commonly applied screening criteria. Although these two corals should be of similar ages, and both pass the screening criteria, their age differs by ~ 20 ka. One coral gives a typical Last Interglacial age of 124 ka, while the younger coral yields apparent ages of 99–105 ka. The apparently younger coral has a uranium concentration that is elevated by approximately 25% over living corals of the same species, a clear example of uranium addition. Reproduced from Thompson WG (submitted). Why the duration of the Last Interglacial is systematically overestimated. *Earth and Planetary Science Letters*.

similar anomalies in aragonitic marine sediments, and a set of decay equations was proposed to correct the ages for the added isotopes (Henderson and Slowey, 2000; Henderson et al., 2001). Building on this work, two new types of approaches have been developed to correct U-series coral ages for open-system isotope addition: modified decay equations and isochron techniques. Isochron approaches (Scholz et al., 2004) rely on the observed empirical relationship between initial $^{234}\text{U}/^{238}\text{U}$ and age. While this technique may be useful in some situations, it relies on the fundamental assumption that all corals used to construct the isochron are the same age. This assumption is often difficult to test. Furthermore, it gives an average age for a suite of samples rather than individual ages for each coral. Modified decay equations (Thompson et al., 2003; Villemant and Feuillet, 2003) assume that isotope addition is related to radioactive decay through alpha-recoil processes or geochemical contrasts between parent and daughter isotopes. The more comprehensive approach (Villemant and Feuillet, 2003) also included the possibility of added initial ^{230}Th and ^{232}Th , but these particular equations incorporated an earlier erroneous assumption (Henderson and Slowey, 2000) that the $^{230}\text{Th}/^{234}\text{U}$ addition ratio was related to the $^{234}\text{U}/^{238}\text{U}$ ratio of the coral that had experienced isotope addition and was found to give erroneous results (Andersen et al., 2008; Frank et al., 2006).

Correcting these mathematical and conceptual problems, a similar set of decay equations was developed to correct coral ages for isotope addition (Thompson et al., 2003). The fundamental concept behind this approach is simple: very small amounts of ^{234}Th and ^{230}Th produced by radioactive decay are mobilized by alpha recoil from the carbonate matrix surrounding corals and are added over time to the measured coral.

This coupled addition of two thorium isotopes, with identical chemical properties, explains the observed correlation of ^{234}U and ^{230}Th (and conventional age) in a geochemically consistent way for the first time. The $^{234}\text{Th}/^{230}\text{Th}$ addition ratio at any given time is determined by the $^{234}\text{U}/^{238}\text{U}$ activity ratio of the source of the added ^{234}Th and ^{230}Th because the amount of ^{230}Th and ^{234}Th mobilized is proportional to the number of decays of ^{234}U and ^{238}U (respectively) occurring there. Therefore, this addition process can be described by a modified set of decay equations (Thompson et al., 2003). The $^{234}\text{U}/^{238}\text{U}$ ratio of modern seawater and the fraction of decays mobilized are constraints for the equations that are derived from high-precision measurements and first principles of physics, respectively. The predicted $^{230}\text{Th}/^{234}\text{Th}$ addition ratios arise directly from the hypothesis that these isotopes are mobilized by radioactive decay and are independent of the empirical trends and not 'tuned' to them in any way. Therefore, the excellent match of the theoretically predicted and empirically observed addition ratios (Figure 1) provides strong validation of the equation's underlying principles. These correction equations have been shown to produce robust and reliable results (Andersen et al., 2008, 2009, 2010; Frank et al., 2006; Stirling and Andersen, 2009; Thompson, submitted; Thompson and Goldstein, 2005, 2006; Thompson et al., 2011).

These results have important implications for conventional U-series coral dating. It is quite clear that the precision of uncorrected conventional U-series ages depends directly on the range of initial $^{234}\text{U}/^{238}\text{U}$ deemed 'acceptable' by the investigator. For example, a commonly quoted criterion of $\pm 0.8\%$ from modern seawater for acceptable initial coral $^{234}\text{U}/^{238}\text{U}$ imposes a ± 3200 -year uncertainty on the reported ages. An additional uncertainty of approximately 800 years

arises from uncertainty in the calculated initial $^{234}\text{U}/^{238}\text{U}$ ratio. Furthermore, very small amounts of U gain or loss can change ages significantly without changing the initial $^{234}\text{U}/^{238}\text{U}$ ratio, further reducing the efficacy of the screening criteria. Screened ages retain a strong bias toward artificially older ages and are not as accurate as the label 'reliable' suggests (Thompson, submitted). The application of this screening criterion results in the rejection of greater than 90% of coral ages measured. Therefore, the use of uncorrected conventional ages in sea level reconstructions degrades both their accuracy and resolution (Thompson and Goldstein, 2005). Furthermore, $^{231}\text{Pa}/^{235}\text{U}$ dating does not provide an independent assessment of the accuracy of U/Th ages. Both the $^{230}\text{Th}/^{238}\text{U}$ and $^{231}\text{Pa}/^{235}\text{U}$ systems will be similarly affected by alpha-recoil mobilization of daughter isotopes and strong contrasts in geochemical behavior between parent and daughter isotopes. In the combined Pa/Th system, this process moves isotope ratios along the $^{231}\text{Pa}/^{230}\text{Th}$ concordia so that the U/Th and $^{231}\text{Pa}/^{235}\text{U}$ ages may be in reasonable agreement even though they are both incorrect. Therefore, this concordance test may fail to reject samples that have behaved as an open system. Corals with concordant Pa/Th ages but clearly disturbed initial $^{234}\text{U}/^{238}\text{U}$ (Cutler et al., 2003) support this theoretical prediction. Furthermore, corals that have experienced small amounts of open-system behavior may have $^{231}\text{Pa}/^{235}\text{U}$ and U/Th ages that disagree significantly simply because the geochemistry of Pa and Th is not identical and these isotopes are fractionated, causing rejection of fairly reliable ages. Corals with seawater initial $^{234}\text{U}/^{238}\text{U}$ and different U/Pa and U/Th ages suggest that this is indeed the case (Cutler et al., 2003). Thus, it appears that initial coral $^{234}\text{U}/^{238}\text{U}$ ratios provide a more reliable test for closed-system conditions than $^{231}\text{Pa}/^{235}\text{U}$ ages.

The advantage of age correction equations is the ability to calculate ages for a large suite of samples, regardless of the degree of ^{234}U and ^{230}Th addition. The reproducibility of ages from a single stratigraphic unit can then provide a direct assessment of the uncertainties involved in the correction procedure, and replicate measurement can also reduce age artifacts due to U gain and loss (Thompson et al., 2011). Correcting coral ages for the isotopic addition of ^{234}Th and ^{230}Th provides a quantitative way of solving the isotope addition problem that is a significant improvement over using initial $^{234}\text{U}/^{238}\text{U}$ as screening criteria for uncorrected conventional ages.

Dating of Speleothems

Speleothems are carbonate cave deposits that form as the result of precipitation from flowing or dripping groundwater. Both evaporation and CO_2 degassing are important processes in the deposition of these carbonate minerals. During their growth, speleothems incorporate a complex suite of isotopes and trace elements that record environmental conditions. Although there are many forms of cave deposits, records from stalagmites and flowstones appear to be the most widely used. Because they precipitate from natural waters where the solubility of uranium is high and the solubility of thorium low, speleothems often have significant uranium concentrations and nearly negligible amounts of thorium. This high U/Th ratio makes these environmental archives attractive candidates for

U-series dating. They have been used in a number of ways to infer past environmental conditions (e.g., Bar-Matthews et al., 1999), and U-series dating of such records provides a radiometric timescale that yields important insights into the timing and mechanisms of global climate change (e.g., Wang et al., 2001). Dating of speleothems has also been used to assess sea level change, landscape evolution, earthquake history, and the age of archaeological remains. The best candidates for U-series dating are composed of dense, columnar, and unaltered calcite. Speleothems appear to be much less affected, if affected at all, by the postdepositional isotope addition processes that complicate U/Th coral dating. This is very likely the result of their dense and nonporous structure. However, the U-series dating of speleothems has its own set of challenges. The resolution of speleothem timescales is ultimately limited by the growth rate of the speleothem, its uranium content, and the number of dates obtained. While continuous growth is commonly assumed between dated portions, it is not clear that such an assumption is warranted because hiatuses between dates may escape detection. At some level of resolution, hiatuses that are not visible will not be detectable because a sample for dating that spans such a hiatus will give an intermediate age, falsely supporting the appearance of continuity. Although the ideal candidates for U-series dating have relatively high uranium content (several ppm) and little or no initial ^{230}Th , significant quantities of initial ^{230}Th are often present due to incorporation of detrital material or a 'hydrogenous' component of dissolved or colloiddally scavenged thorium. Initial ^{230}Th can be assessed in most cases by measuring the common isotope of thorium ^{232}Th . Corrections for initial ^{230}Th are often made by assuming a fixed initial $^{230}\text{Th}/^{232}\text{Th}$ ratio. Alternatively, isochron methods may be applied using subsamples along a growth band. Insight into the initial incorporation of ^{230}Th and ^{231}Pa may also be obtained by measurements on recently precipitated cave calcite. Richards and Dorale (2003) gave a detailed and recent review of U-series speleothem dating.

Introduction

Natural archives of past climates and environments are necessary to improve our understanding of climate change during the Holocene and beyond, and to estimate the degree of human impact on past environments. Instrumental and written (historic) information about these conditions are restricted to the last few centuries and millennia, respectively. Therefore, records that archive datasets about natural (climatic) and human environmental change are relevant to extend our knowledge about trends, variabilities, events, and their forcing factors. This information is also essential to develop and verify climate modeling. For this approach, records of decadal or annual resolution are preferred by paleoclimatologists, because only such records provide proxy data on a timescale relevant to society, that is, with a temporal resolution of less than one human generation (<30 yr). There are only a few types of incrementally dated records that provide this high resolution: varved lake sediment is one of them.

The term ‘varve’ is a Swedish word that means cyclic layer. It was first used in 1862 as *Hvarfig lera* by the Swedish Geological Survey to describe rhythmically deposited clays in a proglacial environment on one of the first geological maps of Sweden.

History

The study of varved lake sediments has a history of more than 150 yr. At the same time that Swedish geologists were mapping varved clays for the first time, alternating pale and dark laminated lake sediments were interpreted as a potential source of chronological information by A. Heim in Switzerland and by E. Hitchcock in North America. But another 50 yr passed until this concept was developed into a useful dating tool, completely different from the common method of stratigraphic classification. It was again in Sweden that the geologist Gerard De Geer applied the chronological information stored in varved clays that were deposited near the margin of the retreating Scandinavian ice sheet to determine the time elapsed since the termination of the Pleistocene. De Geer established a network of sites along the Baltic coast of Sweden and linked them using distinct varve thickness variations (De Geer, 1912). Moreover, he defined the term ‘varve’ as being one complete annual cycle consisting of a coarse-grained pale summer layer

and a fine-grained dark winter layer (Figure 1). He also coined the term ‘geochronology’ and for the first time the annual resolution timescale was used in geology (De Geer, 1912). Varves were regarded as typical deposits related to glacial meltwater entering a proglacial lake.

De Geer was convinced that solar forcing controls meltwater discharge and in turn varve thickness variations. Therefore, De Geer and his followers matched Swedish varve thickness records with records from Finland (M. Sauramo), North America (E. Antevs), and Patagonia (C. Caldenius) to provide additional evidence for the idea of global forcing of varve thickness variations. However, his long-distance correlation (teleconnection) was soon found to be unreliable. This discredited varve chronologies for a long time as they were regarded as a subjective and nonreliable dating tool. The attitude against this incremental dating method was intensified due to the advent of a new, seemingly precise dating method discovered in 1949 – radiocarbon dating.

It was not until the 1970s that varved records started to become of interest again. The discussion of human impact on the environment (eutrophication, acidification, pollution, soil erosion, climate change) needed high-resolution information about the past to allow an extension of the short instrumental records of environmental change and to determine natural background levels. In combination with new coring techniques and more sophisticated analytical tools, varved records became one focus of paleoenvironmental research. For the first time nonglacial lakes were investigated and thus it was only fitting that the term ‘varve,’ so far restricted to proglacial environments, was extended to all annually (seasonally) laminated sediments on the continents (O’Sullivan, 1983; Anderson et al., 1985; Saarnisto, 1986) as well as in the oceans (Kemp, 1996). Since then, the terms ‘varved sediments’ and ‘annually laminated sediments’ have been used as synonyms. Occasionally, for proglacial varves, the terms ‘clastic’ or ‘classic varves’ are used to distinguish them from nonglacial organic or biogenic varves.

Additionally, since the 1980s, it has become increasingly obvious that radiocarbon dating does not provide a calendar year chronology but needs to be calibrated (van der Plicht, 2000). Dendrochronology is the method of choice to calibrate Holocene radiocarbon ages. However, for the Late Glacial and beyond trees are rare or absent and thus annually laminated sediments have been used for calibration (van der Plicht, 2000).

Figure 1 Pleistocene glacial varves cropping out at Eberswalde-Macherslust, Brandenburg, Germany. Note the decreasing varve thickness towards the top as a result of increasing distance from the active ice margin. The scale bar is 30 cm. Photograph by B. Zolitschka.

Varved lake sediments are also ideal to trace past land-use changes if used in combination with archaeological investigations (Hicks et al., 1994). Important societal issues include geological hazards such as earthquakes, volcanic eruptions, or tsunamis, which can be recognized and dated precisely in varved records. More recently, efforts have been undertaken to better understand the processes that cause the formation of varved lake sediments by applying sediment trap studies in lakes (Leemann and Niessen, 1994) in combination with highest-resolution image analysis techniques capable of deciphering the seasonal structure of varves (Francus, 2004).

Formation of Varved Lake Sediments

Annually laminated lake sediments are not typical for the Quaternary and have also been reported for sedimentary sequences as far back as the Paleozoic (Anderson and Dean, 1988). Their variability in space and time, however, is difficult to assess because their formation processes are not well enough understood. This is different for Quaternary and especially for late Holocene records, a time period when predominantly modern processes were active.

The formation of varved lake sediments depends on overall climatic conditions. The main controlling factor is the seasonal variability of temperature and precipitation with amplitudes twice as large as long-term climatic fluctuations. Seasonal climatic variation is responsible for the succession of different life forms in the lake waters and for physical and chemical processes in the lake and its catchment area controlling biological productivity, precipitation of authigenic minerals as well as transport of minerogenic and organic particles from the catchment area to the lake. These natural conditions are dominated by the regional climate and control the prevailing mechanisms of lacustrine sedimentation (Håkanson and Jansson, 1983).

Clastic sediments. Minerogenic particles are carried through fluvial input from the catchment area or by atmospheric deposition to the lake. To a certain degree organic fragments such as

leaves or pieces of wood may additionally be incorporated via runoff.

Biogenic sediments. Biological productivity in the lake generates organic matter that sinks to the lake bottom and accumulates.

Evaporitic sediments. Chemical precipitation of minerals from the water column adds authigenic mineral components.

Sediment constituents are classified into autochthonous (produced in the lake) and allochthonous components (formed in the catchment area). Although there are clear environmental constraints necessary for the formation of the varve types related to these depositional processes, they are mostly the result of a combination of processes. Altogether, the annual rhythm produces an internal clock, which makes varved lake sediments ideal for environmental reconstruction as it provides continuous dating without interpolation, typical for all incremental dating methods. Thus, seasonally changing constituents are deposited, leading to the formation of a characteristic varve structure with at least two laminae that ideally contrast in both color and composition.

Preservation of Varves

Only few lakes are reported to contain long records with annual laminations. This occurs despite a continuous lacustrine sedimentation process with a pronounced seasonal climatic forcing for almost every lake except for equatorial lakes that not necessarily have a clear seasonal signal. The reason for this is that certain internal lake processes can prevent varve preservation:

- burrowing activities of benthic organisms (bioturbation),
- resuspension of bottom sediments through wind- or density-driven lake water circulation, and
- bottom currents that interrupt continuous sedimentation and cause erosional hiatuses.

The latter two processes are excluded if the lake basin is deep with a small surface area and is geomorphologically protected. Such preconditions exclude or reduce strong wind influences and promote varve preservation (O'Sullivan, 1983; Ojala et al., 2000). These morphological features, in combination with eutrophic conditions, favor the formation of anoxic bottom water, which is the result of oxygen depletion related to decomposition of organic matter near the sediment surface. This eventually restricts or excludes the presence of bottom-dwelling organisms and thus eliminates bioturbation. Anoxic conditions can be permanent, as in meromictic lakes (Anderson et al., 1985), or seasonal to preserve annual laminations.

Preconditions for varve preservation are natural or anthropogenic. Cultural eutrophication related to industrialization since the mid-nineteenth century has often generated anoxia in deep lakes initiating the formation of varved lake sediments (Figure 2; Wehrli, 1997; Lüder et al., 2006).

Clastic Varved Lake Sediments

Clastic sediments predominate under cold climatic conditions, such as those found in the Arctic (Figure 3) or in high Alpine regions (Figure 4). Such sediments are typical for proglacial

Figure 2 Varved lake sediments from Greifensee, Switzerland. The upper 26 cm of this freeze core displays the history of cultural eutrophication through the formation of carbonaceous organic varves since 1930. Below 26 cm the productivity of the lake was lower; no oxygen depletion occurred near the lake floor and thus organic matter was not preserved. Photograph by M. Sturm.

and periglacial lakes. Intensive physical weathering and the lack of a densely vegetated catchment area provide high amounts of minerogenic detritus, which is easily eroded and

transported into the lake. The sediment transfer is related to the annual freeze–thaw cycle and the amount of runoff. In regions with a continental climate, runoff is governed by melting of snow and ice through solar insolation during summer. Under oceanic climatic conditions, runoff is controlled either by the melting of snow and ice through advective heat transport or by precipitation. Such lakes are poor in nutrients (oligotrophic), which inhibits high organic productivity and the formation of organic varves.

Clastic varves are formed when a discontinuous (highly seasonal) stream loaded with suspended sediment enters a lake of stratified water (Sturm, 1979). According to its density and in relation to the density of the lake water, the inflowing stream water is positioned in the lake as over-, inter-, or under-flow. Over- and interflows cause a wide distribution of suspended matter across the lake. After entering the lake, the flow velocity of the stream water is transformed into turbulence causing a reduction of transport capacity for suspended sediment particles. Accordingly, coarse particles (sand, silt) are deposited immediately, whereas fine particles (fine silt, clay) remain in suspension until runoff has stopped or the lake is ice-covered. Thus, clastic varves are composed of a pale coarse-grained basal lamina and a darker fine-grained (clay) top lamina (Figure 3) or vice versa (Figures 4 and 5; Table 1). Additional coarse-grained laminae are frequently observed and are often related to successive annual runoff events.

Organic Varved Lake Sediments

Under temperate humid climatic conditions the catchment area is vegetated, reducing the availability and transport capability of clastic material into the lake. Chemical weathering is prevalent and releases nutrients from the bedrock that are incorporated into plant organic matter, buffered in soils, or washed out and transported in dissolved form to the lake. Nutrient rich (eutrophic) conditions in the lake are the consequence. The related increase of organic productivity leads to the formation of organic varves reflecting the lacustrine life cycle (Figures 5 and 6).

In late winter or early spring, mixing of the lake water body (holomixis) distributes nutrients to the photic zone where algal blooms develop. Diatoms mainly start reproducing in spring, followed by green and blue-green algae during summer. Sometimes, after the second annual mixis in fall, diatoms bloom again. A layer of chrysophyte cysts often terminates the lacustrine life cycle (Figures 5 and 6; Table 1). While green and blue-green algae decompose during deposition, siliceous diatom frustules are resistant to dissolution and are preserved in the sedimentary record.

Another component of organic varves are authigenic calcites. Carbonaceous laminae are present if limestone or limy particles of unconsolidated till or loess deposits are dissolved and transferred via runoff into the lake (Figures 2, 5, and 7). In such hard-water lakes calcite crystals are precipitated. Ca^{2+} and (HCO_3^-) stay in solution in the lake water until their saturation point is reached. This is partly achieved by the seasonal temperature increase in the surface water during insolation maxima in summer. As CaCO_3 decreases in solubility with temperature, calcite may precipitate due to this effect alone. However, the temperature-related increase of photosynthetic

Figure 3 Clastic varves of Lake C2, north coast of Ellesmere Island, Canadian High Arctic. The microscopic photograph of nonglacial clastic varves shows the undulated sediment–water interface in normal (left) and polarized light (right). Pale and coarse-grained laminae are related to snowmelt runoff events during summer, which contrast to the dark fine-grained laminae on top that settled out of suspension during winter under ice cover. Photographs by B. Zolitschka.

Figure 4 Nonglacial clastic varves of Alpine Brienzersee, Switzerland. Varve counts are marked and labeled; the scale is in cm. The marker years (1963, 1986) determined by radiometric dating (^{137}Cs) are highlighted as well as the sediment surface (2004). Photograph by M. Sturm.

activities in the water column through phytoplankton blooms is more important. Accordingly, CO_2 is withdrawn from the water, pH rises up to 9, and CaCO_3 solubility is reduced. Thus, the combination of temperature increase and phytoplankton activities adds another autochthonous component to organic varves – white carbonate laminae (Figure 5 and Table 1).

In addition to these autochthonous sedimentary components, an allochthonous component to organic varves may also occur during winter. As plant cover is reduced and soils become more susceptible to erosion, runoff increases, especially after fall and winter rain events. This transports minerogenic as well as (littoral and terrestrial) organic debris to the lake (Table 1).

Evaporitic Varved Lake Sediments

Under arid or semiarid climatic conditions evaporitic varves (Figure 8) may be formed if the salinity and pH of the lake water increase through enhanced evaporation. This causes the saturation of specific mineral compounds (salts), which precipitate out of the water column. In addition to calcite, which can precipitate either biogeochemically in mid-latitudes (organic varves) or physicochemically under semiarid climatic conditions, evaporitic varves are composed of aragonite, gypsum, and halite. They are typically composed of a pale–dark couplet (Figure 8 and Table 1). The pale lamina is attributed to salt precipitates, whereas the dark lamina is related to runoff events introducing a mixture of minerogenic and organic detritus. Runoff occurs during the less arid part of the year, usually during winter.

Varve Chronology and Applications

Varved lake sediments are ideal sources of paleoenvironmental and paleoclimatic data because:

- varves provide an internal, continuous time frame in calendar years (Figure 4);
- radiometric dating and sometimes tephrochronology or OS� dating can be applied to the same record (multiple dating approach) to independently verify the varve-based age model (Zolitschka et al., 2000);
- variations in varve thickness (Figure 9) and related microfacies analyses provide a continuous dataset of information with highest possible time resolution if the local processes of varve formation are known;
- quantified flux rates for the entire record can be precisely determined, based on the continuous chronological information and in combination with dry density measurements; and
- precise time control and flux rates improve supplementary analyses carried out on discrete (noncontinuous) subsamples such as sedimentological, micropaleontological (pollen, diatoms, chrysophytes, chironomids, ostracods), geophysical, or inorganic and organic geochemical analyses.

However, each studied proxy parameter is only one piece in a big puzzle with an indeterminable number of jigsaw pieces. The total number of pieces needed to understand the full range

Table 1 Different varve types with idealized composition, color, and timing of corresponding seasonal laminae

	<i>Clastic varves</i>	<i>Organic varves</i>	<i>Evaporitic varves</i>
Spring		First Diatom bloom (pale)	
Summer	Coarse-grained minerogenic particles via runoff (pale or dark)	Calcite precipitation (white, optional)	Precipitation of calcite, aragonite, gypsum or halite (white)
Late summer		Second diatom bloom, chrysophytes cysts (pale, both optional)	
Fall/winter	Fine-grained minerogenic particles out of suspension (dark or pale)	Organic and minerogenic detritus via runoff (dark)	Organic and minerogenic detritus via runoff (dark)

of complex environmental variability is site-, time- and proxy-specific and thus varies even within the same record.

The annual character of laminations needs to be verified for the study of varved lake sediments and prior to establishing a varve chronology. This includes error estimations. Finally, environmental reconstruction builds upon this temporal framework.

Varve Verification

Before varves are counted and their thickness measured it is necessary for every specific site to develop a conceptual and mostly idealized model about the processes that formed the different varve laminae (Figure 5; Lamoureux, 2001). This varve model depends on limnological conditions as well as on environmental conditions in the catchment area. It should characterize specific features in varve composition, which are later used to determine boundaries between consecutive varves and to identify laminae of no chronological meaning (turbidites, homogenites). This approach is especially important if varves cannot be easily distinguished. The development of such a process-oriented varve model (Figure 5) should ideally be supported by sediment trap studies (Leemann and Niessen, 1994) and micropaleontological methods, for example, by investigating the succession of pollen types or diatom species

during one year (Card, 1997; Hausmann et al., 2002). A varve chronology can only be established if the structure of the varve cycle is clear.

Varve Chronology

After determination of the annual structure, the varve chronology is established through replicate varve counts and thickness measurements along at least three transects (Lamoureux, 2001). This is usually performed either via microstratigraphical (microscopic) analysis of thin sections (Brauer, 2004) or via techniques related to image analysis (Francus, 2004). Both methods have their own characteristic advantages: microstratigraphic investigation allows the analysis of internal structure and composition (microfacies) of every individual varve, whereas image analysis techniques provide more objective and faster results. Based on thickness measurements of every individual varve (Figure 9), the age–depth model (varve chronology) is established with as many data points as varves that have been counted.

Varve chronologies are regarded as absolute chronologies, if they are continuous and extend to the sediment surface. However, in many cases, inconsistencies of the chronology or hiatuses have been detected. Such often-encountered difficulties

Figure 6 Organic varved lake sediments from Holzmaar, Eifel, Germany. A, The macroscopic photograph shows organic varves composed of diatoms (pale laminae) and organic detritus (dark laminae); B, The microscopic photograph with normal light (right) shows the internal structure of these organic varves with massive planktonic diatom blooms in pale laminae and larger benthic and epiphytic diatoms in dark laminae. Photographs by B. Zolitschka.

can only be overcome by applying additional independent chronological methods (multiple dating approach). Usually, these include radiocarbon dating (^{14}C) and, less extensively, OSL dating. In addition, stratigraphic methods are applied to provide another line of evidence in support of time control and to facilitate regional correlation. Most common among these is palynology from which distinct changes in regional patterns of vegetation are derived (biostratigraphy). For a larger, regional scale, paleomagnetic studies are ideal because they reveal global variations of the Earth's magnetic field (magnetostratigraphy). In volcanically active regions, tephra layers provide another means of developing an independent time frame (tephrochronology). Altogether, multiple dating significantly improves the accuracy of dating (Zolitschka et al., 2000).

Sometimes the connection of varved sediment records to the present day can be problematic. This is checked with radiometric dating (^{137}Cs , ^{210}Pb) or by comparing the record with historic data or events (Lüder et al., 2006). Varve chronologies are called floating chronologies, if they cannot be connected to the present day.

Error Estimations

Systematic errors of varve chronologies (Sprowl, 1993) are attributed to different sources.

Technical problems. These errors are caused by incomplete core recovery (sediment gaps as the result of coring artifacts) or incorrect correlation of core segments.

Figure 9 Varve thickness measurements (cf. Fig. 6) of four parallel sediment sequences (blue) from Holzmaar, Eifel, Germany. Each core is offset by a factor of 10 to separate the plots. early Holocene varves were counted and measured using thin sections by two different persons (HLM-B/C by B. Zolitschka; HLM-1, HLM-2, and HLM-3 by B. Rein). In the bottom panel the stacked varve record is displayed in red reflecting the climatic fluctuations of the Preboreal Oscillation (11,400–11,000 cal. BP) and the Boreal Oscillation (10,500–10,200 cal. BP); both fluctuations show markedly thicker varves related to increased minerogenic sediment input via runoff.

Depositional events. Such errors occur as the result of erosion (erosive turbidites, volcanic ash layers), deposition of plant or animal macrofossils (e.g., tree trunks or animal carcasses), or drop stones, and are restricted to certain areas on the lake floor.

Sedimentation rates. The occurrence of very high (>20 mm) or very low (<0.2 mm) varve thickness makes the individual annual layer difficult to distinguish. Thick varves are generally composed of many seasonal laminae (sometimes >10, related to rainfall or runoff events), which are hard to distinguish from the annual cycle. Thin varves show the opposite: laminae within the annual cycle are extremely thin, difficult to determine, or even missing. For these varves, the entire annual cycle is easily mistaken as a lamina of a seemingly thicker varve.

Varve preservation. Changes in lake level or autochthonous productivity have significant effects on anoxic bottom water conditions and thus on varve preservation (Figure 2). Periods with well-preserved varves may thus alternate with periods of no varve preservation.

Technical problems as well as depositional events can often be avoided by a careful selection of coring sites. Moreover, potential errors can be minimized by applying appropriate coring techniques and recovering several parallel and overlapping core series from the same lake (Figure 9) that are matched and cross-dated. The other errors mentioned are difficult to circumvent and often must be regarded as an inherent problem

to varve chronologies. This increases the importance of cross-checking varve chronologies against other independent dating methods following the multiple dating approach.

If varves are well developed and not disrupted, replicate counts show only little variation between different counts and observers (Figure 9; Ojala and Saarnisto, 1999). The counting error will be low. But if varved sediments are disturbed or not very distinct, counting errors increase (Tian et al., 2005). Generally, the determination of errors as variance between different investigators or replicate counts gives only a measure for the studied section. It does not provide any indication about the chronological error of the entire record, which is mostly the result of undetected systematic errors. Such errors can only be determined either by applying the multiple dating approach or by comparing environmental reconstruction with other well-dated records.

Paleoenvironmental Reconstruction Based on Varved Lake Sediments

Recently, multiproxy investigations of varved lake sediments became common because they provide well-dated independent lines of evidence for environmental change as response to climate change and human impact and thus considerably improve the possibilities for interpretation. Several

compilations concerning annually laminated sediments covering methodological aspects as well as interdisciplinary approaches to paleoclimatic and paleoenvironmental interpretation give an overview about possibilities and restrictions and are suggested for further reading. Special issues on individual lakes are available for Elk Lake, Minnesota (Bradbury and Dean, 1993), Lake C2, Canadian High Arctic (Bradley, 1996), Baldeggersee, Switzerland (Wehrli, 1997), and Lake Gosciąz, Poland (Ralska-Jasiewiczowa et al., 1998). Additionally, five volumes are dedicated to methods and applications of varved sediments: an introduction to the formation and composition of clastic varves (Schluchter, 1979), methods and case studies of laminated lacustrine sediments throughout Europe (Saarnisto and Kahra, 1992), the significance of varved lake sediments for the study of human impact on the environment (Hicks et al., 1994), applications of laminated sediments as paleoindicators (Kemp, 1996), and the calibration of radiocarbon dates using varve chronologies (van der Plicht, 2000).

Conclusion

Time control is one of the most important issues for the study of the Quaternary. Without an accurate timescale it is impossible to compare instrumental, historical, and archaeological data as well as other proxy records from natural archives such as lakes, tree rings, ice cores, peat bogs, speleothems, oceans, or corals on a local, regional, or global scale. Of all sedimentary records, varved lake sediments provide the best possibility of solving these chronological concerns. In addition to a precise and reliable high-resolution timescale, varved lake sediments are usually studied in an interdisciplinary way including sedimentological, geochemical, geophysical, and biological methods, combined within the field of paleolimnology (Berglund, 1986; Last and Smol, 2001). Therefore, such records provide a unique opportunity to study the dynamics of past environmental systems on various spatial and temporal scales. This perspective is necessary to realistically estimate future changes, changes of the environmental system that are at least partly the result of human activities and which will definitely influence the future of human societies.

Introduction and History

The study of varved sediments has a long history extending back more than 150 years. The term varve is a Swedish word that means cyclic layer. It was first used in 1862 as 'Hvarfig lera' by the Swedish Geological Survey to describe rhythmically deposited clays in a proglacial environment on one of the first geological maps of Sweden. At the same time when Swedish geologists mapped varved clays for the first time, alternating pale and dark laminated lake sediments were interpreted as a potential source of chronological information by A. Heim in Switzerland and by E. Hitchcock in North America. But another 50 years passed until this concept was developed into the first dating tool, completely distinct from the common stratigraphic classification. It was again in Sweden that the geologist Gerard De Geer applied the chronological information stored in varved clays that were deposited near the margin of the retreating Scandinavian ice sheet to determine the time elapsed since the termination of the Pleistocene. De Geer established a network of sites along the Baltic coast of Sweden and linked them using recognizable variations in varve thickness (De Geer, 1912). Moreover, he defined the term varve as being one complete annual cycle consisting of a coarse-grained pale summer layer and a fine-grained dark winter layer (Figure 1). In addition, De Geer coined the term geochronology and for the first time introduced a temporal unit (the year) to geology (De Geer, 1912). Following his work, varves were regarded as typical deposits related to glacial meltwater entering a proglacial lake.

De Geer was convinced that solar forcing controls meltwater discharge and in turn varve thickness variations. Therefore, De Geer and his followers matched Swedish varve thickness records with records from Finland (M. Sauramo), North America (E. Antevs), and Patagonia (C. Caldenius) to provide additional evidence for the idea of global forcing of varve thickness variations. However, his long-distance correlations (teleconnection) were soon discredited, resulting in a period of reduced trust in varve chronologies, such that they were regarded as a subjective and nonreliable dating tool. The attitude against this incremental dating method was intensified due to the advent of a new seemingly precise dating method discovered in 1949 – radiocarbon dating. It was not before the 1970s that varved records started to become of interest again. The discussion of human impact on the environment (eutrophication, acidification, pollution, soil erosion, climate change) needed high-resolution information about the past to allow an extension of the short instrumental records of environmental change and to determine natural background levels. In combination with new coring techniques and more sophisticated analytical tools, varved records became one focus of paleoenvironmental research. At that time, predominantly nonglacial lakes were being investigated, and it was only subsequent to this that the term varve, so far restricted to proglacial environments, was

extended to all annually (seasonally) laminated sediments on the continents (O'Sullivan, 1983; Saarnisto, 1986) as well as in the oceans (Kemp, 1996). As a result, the terms varved sediments and annually laminated sediments are now used as synonyms.

Varve Formation and Preservation

Varved sediments are created primarily through the interplay of two processes: seasonal variations in the genesis, transport, and deposition of sediments, and the preservation of that signal after burial. A strong seasonal cycle that influences sedimentation is the fundamental process controlling varve deposition. In most settings, this is not a limiting factor because a dominant seasonal climate cycle with large impacts on the environment, particularly the hydrological cycle, can be found nearly everywhere. In temperate climates, for example, surface water runs freely in summer and freezes over in winter, greatly varying the amount of energy available for clastic sediment transport. Similarly, in the tropics, monsoons create dramatically different runoff during wet and dry seasons. Of course, biology also follows seasonal cycles, and this influences sedimentation. Diatoms in freshwater lakes bloom during spring and summer and die out in winter, and production based on marine upwelling may fluctuate seasonally following movements of zonal winds. Such manifestations of seasonality result in different sedimentary regimes, delivering biological or mineralogical material to the sediment surface at different times of year as distinct layers (e.g., Cook et al., 2009; Francus et al., 2008; Ojala et al., 2000).

Seasonal sediment layers are produced and deposited in many environments, but are usually disturbed by bioturbation from benthic organisms, as well as sediment mixing and resuspension due to slumping and current action. In order for varves to be preserved, the fragile seasonal layers must remain intact after deposition. In lakes, morphometry of the basin is one of the most important features controlling laminae preservation, as it affects the potential for sediment disturbance. A relationship exists between lake area and depth in those sites with preservation of laminated sediments (O'Sullivan, 1983). In general, very deep lakes or lakes with small surface area that have great *relative* depth will avoid deep wind mixing and thus resuspension of surface sediments. Basin morphometry is also critical with respect to another important aspect controlling varve preservation – oxygenation of bottom water. Deep lakes allow development of strong thermal stratification, reducing ventilation of bottom water. Oxidation of organic matter falling through the water column then depletes available oxygen and the deep waters become anoxic, preventing the growth of benthic organisms and the influence of bioturbation. Physical isolation of bottom waters can also occur in the ocean, in shallow-silled marine basins formed as deep fjords such as

Figure 1 Pleistocene glacial varves cropping out at Eberswalde–Macherslust, Brandenburg (Germany). Note the decreasing varve thickness toward the top of the section as a result of increasing distance from the active ice margin. The scale bar is 30 cm. Photograph by B. Zolitschka.

the Saanich Inlet, British Columbia (Blais-Stevens et al., 1997) or as tectonic basins such as the Santa Barbara Basin, California (Behl and Kennett, 1996), Cariaco Basin, Venezuela (Peterson et al., 2000), and Guaymas Basin, Gulf of California (Calvert, 1966). Water column stratification occurs due to chemical as well as thermal processes, such as the juxtaposition of water masses with different salinity. This situation can be found in coastal tidewater lakes where saltwater introduced at high tides is overlain by a freshwater cap from continual stream input (Hughen et al., 1996a). Dense, hypersaline bottom waters can also form from dissolution of exposed salt formations on the seafloor, as is found in the Orca Basin, Gulf of Mexico (Kennett et al., 1985). Although not absolutely required for varve formation, anoxic bottom waters are one of the best indicators of potentially laminated sediments and are often used to help guide coring expeditions. For example, anoxic bottom waters occur where the oxygen minimum zone intersects the seafloor on the continental slopes, and annually laminated sediments have been located and studied off the coast of Pakistan (Schultz et al., 1998) as well as California (Anderson et al., 1987) and Peru (De Vries and Schrader, 1981).

Classification and Morphology

For convenience, varves can be classified into basic types according to the most prominent seasonal feature or layer components. The earliest recognized and most commonly studied varved sediments are *clastic varves*, composed primarily of allochthonous mineral grains that differ seasonally in grain size (De Geer, 1912; O'Sullivan, 1983; Saarnisto, 1986). Clastic varves are common in glacial marine and lacustrine settings where mineral grain production and deposition rates are high, and biological productivity is low. A magnified image of clastic

Figure 2 Photomicrograph of clastic varve couplets from glacial Donard Lake, Baffin Island, core 95DON-05, 47 cm. The sediment surface is toward the top of the photo. Scale bar is 1 mm. Photograph by K. Hughen.

varves from an Arctic lake (Figure 2) illustrates typical sedimentary structures and fabric in this type of varve. The sediments consist of couplets of a light-colored, coarser-grained layer covered by a thin dark layer. Grains as large as fine sand mark the bottom of the coarse layer and grade upward into silt-sized particles, whereas a dark layer of fine clays caps the top of each couplet (Moore et al., 2001). The silts grade gradually upward into the fine clays, but the boundary between the clays and the overlying coarse grains is typically sharp (Figure 2).

The succession of fine sands to silts in a thick layer, topped by a thin clay cap, is the classic structure of glacial varves (Cockburn and Lamoureux, 2008; De Geer, 1912; Francus et al., 2008; Leemann and Neissen, 1994; Moore et al., 2001; O'Sullivan, 1983; Retelle and Child, 1996; Saarnisto, 1986; Wohlfarth et al., 1998; Zolitschka, 1996a). The upward gradation from relatively coarse to fine grains in the thick layer results from a decrease in the energy available for sediment transport during the summer months. During the spring meltwater freshet, runoff is at a maximum and sands and silts previously locked up in winter ice are first available to be transported. Glacial runoff continues throughout the summer, but with snow cover mostly melted, the flux of runoff and energy of transport are diminished, and the size of grains washed into the basin is reduced (Hardy, 1996; Retelle and

Child, 1996). During winter in glacial environments, surface water freezes and transport of sediment is greatly reduced or ceases altogether. In the absence of continual mixing, fine, clay-sized particles suspended in the water column settle out and form an independent dark clay layer. This idealized sequence can be interrupted by abrupt events such as intense rainstorms during the late summer or fall, when an increased pulse of runoff from a rainstorm can result in a sublaminae of larger grains, often recognizable as an anomalous sand lens (Hardy, 1996; Lamoureux, 1999; Lamoureux et al., 2006; Moore et al., 2001; Retelle and Child, 1996). Other sublaminae structures may result from ice rafting or other processes (Tomkins et al., 2009). However, the most diagnostic part of the sediment fabric is the clay cap, usually used to distinguish consecutive years' accumulation.

Another widely studied type of varved sediments are termed *biogenic* (O'Sullivan, 1983; Saarnisto, 1986) or *biochemical varves* (Lotter, 1991). Biogenic varves form due to distinct pulses of aquatic biological productivity, including seasonal plankton blooms (Ojala et al., 2000). The biological layer may interrupt and temporarily dilute a more constant rate of background deposition, such as mineral grains from steady stream flow or eolian input, or else alternate with a different distinct pulse of sedimentation, for example, mineral grains from monsoonal river runoff. A magnified image of biogenic varves from a coastal Arctic tidewater lake illustrates an example of these seasonal layers (Figure 3). The biogenic layers form during the ice-free summer months, and during the winter, suspended particles settle out of the frozen, low-energy environment and are deposited as dark-colored, clay-rich layers (Hughen et al., 1996a, 2000a). Biogenic laminae form in a variety of marine and lacustrine environments, and in many cases a succession of distinct sublaminae can be deposited as different diatom species bloom throughout the growth season (Dean et al., 1999).

Varves may also form through seasonal changes in the physical and chemical properties of the water column, and are usually restricted to lakes. *Calcareous varves* may form in lakes with high CO_3^{2-} content, when calcite layers precipitate out of solution during summer warming (Lotter, 1991; O'Sullivan, 1983). *Ferrogenic varves* may form due to changes in redox conditions affecting the solubility of Fe species and the formation of sulfides versus hydroxides throughout the year (O'Sullivan, 1983). *Evaporite varves* may form as interbedded laminae of precipitates in shallow evaporite basins, and can consist of couplets of calcite and anhydrite (e.g., Castile Formation; Anderson and Dean, 1995), or aragonite with eolian grains (e.g., Lake Lisan; Katz and Kolodny, 1989), depending on water chemistry.

Analytical Techniques

Sampling and Image Analysis

The study and use of varves in geochronology requires special techniques for the recovery and analysis of fragile unconsolidated sediments. The sediment–water interface must be recovered intact to provide a baseline for dating, as well as calibrating the annual climate signal. Specialized sediment-coring methods have been developed for the intact recovery

Figure 3 Photomicrograph of biogenic varve couplets from Ogaq Lake, Baffin Island, core 91-2b, 73.5 cm. The sediment surface is toward the top of the photo. Scale bar is 100 μm . Photograph by K. Hughen.

and preservation of fine laminated structures and the sediment–water interface in soupy sediments. One method is freeze coring, in which a hollow tube filled with a dry ice–alcohol slurry is inserted into soft sediments (Shapiro, 1958). The freeze corer is left in place long enough to allow the sediments and interstitial water to freeze onto the outside of the corer, perfectly preserving the sediment–water interface and uppermost, porous ($\geq 99\%$ water) laminae (Hughen et al., 1996a). Freeze coring requires intensive logistics for bringing large quantities of dry ice into the field and maintaining the cores in a frozen state during transport back to the lab. In some sediments, freezing causes ice crystal disturbance of the fine laminae microstructure, rendering the technique unsuitable for high-magnification analyses (Pike and Kemp, 1996).

Another coring technique successfully used to recover the intact sediment–water interface involves the careful recovery and subsampling of dredges or box cores (e.g., Zolitschka, 1996a), or else the use of a closed-top, miniature gravity corer such as the 'Glew' corer (Glew, 1991). These techniques allow the researcher to raise fragile laminated sediments unfrozen to the surface, but require special handling to ensure that the sediments remain undisturbed during sampling or, much more difficult, transport back to the lab. Typically, this requires carefully siphoning off overlying water right down to

the sediment surface. The cores must be left upright and undisturbed for a sufficient time to allow them to dewater, and the siphoning repeated until no further dewatering is observed. Although time intensive, this method offers an additional advantage over freeze coring in that the effects of porosity are largely removed, whereas the freezing of layers *in situ* requires later corrections for decreasing porosity with depth when making layer thickness or mass flux measurements (Hughen et al., 2000a).

Following successful recovery of varved sediment cores, several techniques are available for investigating the annual laminations, including obtaining high-resolution images of laminae and their internal microfabric and composition. Initially, split core surfaces (or varves exposed in outcrops) may be investigated using noninvasive techniques such as photography, digital imaging, or x-radiography (Schaaf and Thurow, 1994; Zolitschka, 1996b). These techniques are often used in combination to overcome limitations inherent to single methods (e.g., blurring in x-rays due to three-dimensional distortion of laminations). Digital imaging, whether digitization of existing photographs and x-ray film or directly from the sediment surface, allows sophisticated image analysis techniques to aid in the identification of fine laminae (Schaaf and Thurow, 1994; Schultz et al., 1998; Zolitschka, 1996b). For an in-depth review of digital imaging techniques for sediment analysis, see Francus (2004) and articles therein.

Microscopic analysis of unconsolidated sediments requires that the sediments be embedded in epoxy resin and prepared into petrographic thin sections. There are numerous embedding methods used to remove water from microscopic pore spaces and replace it with resin, without disturbing sediment microfabric. The two principle techniques involve either using acetone to initially displace the water, and then resin to replace the acetone (fluid displacive – Clark, 1988; Lamoureux, 1994; Pike and Kemp, 1996), or freeze-drying the sediment to remove water, and then adding resin to the dried sediment block (Hughen et al., 1996a). Freeze-drying is a fast and economical way to prepare sediments for embedding. However, depending on sediment type, freeze-drying can allow minor disturbance of grains at the intralaminae scale and disruption of internal laminae fabrics. Fluid displacement is the least disruptive embedding technique and is recommended for analyses involving internal laminae fabric and *in situ* composition. For detailed reviews of sediment preparation and analytical techniques for varved sediment studies, the reader is referred to Lamoureux (1994), Pike and Kemp (1996), and Dean et al. (1999).

Individual laminations down to mm-scale can usually be discerned using unmagnified images. In order to construct reliable varve chronologies, however, care must be taken to avoid misidentification of 'event deposits' such as turbidites or rainstorm sediment pulses as an entire year's deposition. Such event deposits often possess characteristics of composition or fabric that distinguish them from typical varve couplets (or triplets), including homogenous structure (lacking sublaminae), mixed composition of normally distinct laminae types, anomalous grain size and sorting, and many others (Dean et al., 1999; Hughen et al., 1996b; Lamoureux, 1999). Discrimination of fabrics and compositional elements at the intralamina scale requires powerful techniques for high-resolution and high-magnification sediment analysis, primarily

optical and electron microscopy. Transmitted-light optical microscopy can reveal details of fabric such as sublaminae and grading, as well as grain size, sorting, and the nature of laminae boundaries (Hughen et al., 1996b; Lamoureux, 1999; Pike and Kemp, 1996). For the highest-resolution analyses, scanning electron microscopy, and back-scattered electron imagery in particular (Kemp, 1996), provide the best technique for determination of laminae and sublaminae fabric and structure, as well as details of composition at the scale of individual mineral grains. For example, back-scattered electron imagery can be used to identify the seasonal sequence of diatom species as recorded in distinct sublaminae within 1 year's deposition (Pike and Kemp, 1996). Such high-resolution studies provide critical insights aiding in the interpretation of laminated sediments, both for chronological and paleoclimatic applications. Recent advances in sediment analysis have been introduced by Francus et al. (2002) who analyzed individual clastic grains for size and geometry, providing a more precise indicator of energy of runoff, air temperature, etc.

Independent Dating and Age Control

Before laminated sediments can be counted and used to construct calendar-age chronologies, it must be demonstrated using independent dating techniques that the laminae couplets are indeed annually deposited varves. Simply identifying and counting laminae couplets can lead to misinterpretation of event deposits as seasonal layers, or the counting of layers representing seasonal processes, but ones that do not occur on a regular basis from year to year. Numerous studies have used independent dating techniques to demonstrate that supposed 'varves' were not in fact annually deposited (e.g., Crusius and Anderson, 1992). Whenever possible, a combination of several dating methods should be used both to increase confidence and to provide temporal coverage over a broader range of time scales. Lead-210 is a radioactive isotope resulting from U-series decay with a relatively short half-life (22.3 years). Unsupported ^{210}Pb falls out from the atmosphere (in contrast to supported ^{210}Pb that comes from continuous, *in situ* uranium decay within the buried sediments) and is deposited globally in lake and marine sediments (Appleby and Oldfield, 1978). Excess (unsupported) ^{210}Pb concentrations can be measured precisely by decay-counting methods (Hughen et al., 1996a), providing age control over the past ~150 years. Measurements must be made deep enough to reach background, supported ^{210}Pb levels, and the ^{210}Pb activity should show an exponential decay (Figure 4). These criteria reveal a simple depositional regime (i.e., no turbidites, erosional unconformities, or sudden shifts in sedimentation rate) that can be used to calculate sedimentation rates. A comparison of ^{210}Pb and varve-based sedimentation rates should reveal good agreement in slope, supporting the interpretation of the laminations as annual (Figure 4).

In some cases, the ^{210}Pb dating method may lack the precision necessary to adequately constrain annual varve chronologies. Another technique widely used to precisely date sediments with near-annual resolution is to measure nuclides produced by atmospheric nuclear weapons testing and nuclear reactor accidents. Common nuclides used to identify the 'bomb spike' resulting from the peak of weapons testing in

Figure 4 ^{210}Pb dating method used to confirm varve chronology in sediment core 93-7, Upper Soper Lake, Baffin Island. Excess ^{210}Pb shows good agreement with exponential curve and reaches a plateau at background, supported levels, indicating a simple sedimentation regime without hiatuses or large changes in sedimentation rate. ^{210}Pb ages show good agreement with varve ages versus depth, supporting the hypothesis that the laminae couplets are annually deposited varves. Redrawn from Huguen KA, Overpeck JT, and Anderson RF (2000) Recent warming in a 500-year paleotemperature record from varved sediments, Upper Soper Lake, Baffin Island, Canada. *The Holocene* 10: 9–19.

Figure 5 ^{137}Cs dating method used to confirm varve chronology for sediment core NL2, Nicolay Lake, Cornwall Island. Continuous ^{137}Cs measurements show distinct peaks from nuclear bomb testing in 1963 and the Chernobyl reactor accident in 1986. Close agreement between these known age horizons and varve ages with depth supports the interpretation of the laminated sediments as annual varves. Redrawn from Lamoureux SF (1999) Catchment and lake controls over the formation of varves in monomictic Nicolay Lake, Cornwall Island, Nunavut. *Canadian Journal of Earth Sciences* 36: 1533–1546.

1963 are cesium-137 (^{137}Cs) and plutonium ($^{139+140}\text{Pu}$; Bis-caye et al., 1988). In addition to the bomb-spike, ^{137}Cs from the Chernobyl reactor accident in 1986 can be identified in sediments across the globe (Lamoureux, 1999). In order to test a varve chronology, a high-resolution sequence of ^{137}Cs or Pu measurements must be used to identify the known activity peaks in 1963 and 1986, and the depths of these time horizons compared to the corresponding depths in the varve chronology (Figure 5). Although it is possible to calculate sedimentation rates without obtaining the uppermost sediments for ^{210}Pb dating, for this ^{137}Cs (Pu) method, it is critical to recover a

sediment time marker of absolute known age, usually the undisturbed sediment–water interface. Because of the large amplitude of the production spikes, the main limitation to the precision of the ^{137}Cs and Pu methods is the sampling resolution and sample size needed for measurements.

Chronology Construction

By their nature, varves are a result of changing sediment supply to a depositional basin, and should be present and recognizable throughout that basin. Subtle disturbances may disrupt or

distort the varve sequence recovered in single sediment cores, however, and numerous steps are necessary to create a reliable annual chronology from laminated sediments. In constructing a varve chronology, many of the principles used in dendrochronology must be applied. For example, multiple measurements of varves (tree rings) from a single core (tree) must be averaged, followed by cross-correlation and averaging between multiple cores to build a chronology representative of an entire sediment basin (stand of trees). Small fluctuations in varve thickness as seen in thin sections require that each lamination be measured several times and averaged to provide an objective, representative record from each sediment core (Zolitschka, 1996a). In addition, local disturbances such as turbidites and erosional scours, as well as core breaks or gaps arising from the sampling process, may limit the physical integrity of a record from any single sediment core. To minimize these sources of error, it is critical to correlate varve chronologies constructed from multiple different cores and produce a basin-wide average (Hughen et al., 2000a; Zolitschka, 1996a). Downcore patterns of variation in varve thickness are usually quite distinct and can be recognized in cores across a basin (Figure 6). Cross-correlation of these marker patterns allow the identification and bridging of missing or disturbed sections in single cores. A larger number of cores used for cross-correlation increases the

likelihood of avoiding all core gaps and constructing an accurate and reliable varve chronology.

Varve Applications

Geochronology

The geochronological applications of varved sediments are too numerous to provide an exhaustive list. One significant application that should be emphasized is the calibration and development of other geochronological tools, specifically, calibration of the radiocarbon time scale. Varves from lakes and marine basins have been one of the primary tools used to provide calendar-age calibration of ^{14}C ages beyond the limit of tree rings, >12 000 years ago (Hughen et al., 2000b). Annual calendar-age varve chronologies also provide accurate dates for specific sedimentological events, as well as age models for continuous sediment time series. An example of a study investigating discrete events would be paleoseismology. Earthquakes cause turbidity flows and turbidite deposits that in the proper setting can be dated by counting overlying varves (Hughen et al., 1996b). Interbedded sequences of varved sediments and massive turbidites can be used to determine recurrence intervals of earthquakes in a specific region (Blais-Stevens et al., 1997). Varved sediments have been used to date other types of episodic events such as hurricanes (Besonen et al., 2008) and jökulhlaups (Lewis et al., 2009).

Varve chronologies offer an excellent means for constructing age models for high-resolution paleoclimate records (Augustsson et al., 2010; Enters et al., 2010; Rolland et al., 2009) as well as other time series such as paleogeomagnetic variations (Ojala and Tiljander, 2003; Snowball et al., 2007). Varves are based on seasonal cycles, similar to tree rings and ice-core layers, and do not require calibration in order to provide calendar ages. Varves are therefore well-suited to studies comparing the relative timing and lead-lag relationships of rapid climate changes in different regions, based on high-resolution paleoclimate records with calendar-age chronologies from varved sediments, tree rings, and ice cores (Hughen et al., 2000b). In addition, varve chronologies are built up from fine annual layers, and do not need to be interpolated between infrequent datums such as radiocarbon dates. This provides increased precision at the annual scale and is particularly well suited for studies involving spectral analysis at short (subdecadal) periodicities. Several studies have recently used varved sediments to investigate the past periodicities and frequency behavior of natural systems such as the El-Niño Southern Oscillation, and the North Atlantic Oscillation (Godsey et al., 1999; Rittenour et al., 2000).

Applications Other than Dating

In addition to having geochronological applications, varved sediments may themselves contain valuable paleoenvironmental information. For example, hydrological and sedimentological process studies in glacier-fed lakes have shown that the fluxes of runoff and suspended sediment, as well as varve thickness, vary logarithmically as a function of average temperature during the snow or glacier melting season (Hardy, 1996; Leemann and Neissen, 1994; Retelle and Child, 1996).

Figure 6 Lamination thickness variations in six cores from Lake C2, Ellesmere Island. Data represent five individual measurements of each lamina from thin sections. Gaps in the records indicate missing or disturbed laminations. Redrawn from Zolitschka B (1996) Recent sedimentation in a high arctic lake, northern Ellesmere Island, Canada. *Journal of Paleolimnology* 16: 169–186.

Downcore records of clastic varve or clastic laminae thickness from both glacial and nonglacial lakes correlate well with average summer or snowmelt season temperatures (Hardy et al., 1996; Hughen et al., 2000a; Leemann and Neissen, 1994; Moore et al., 2001; Wohlfarth et al., 1998) and can be used for annually resolved reconstructions of paleotemperature. Other studies have correlated specific forms of sublaminae with runoff and precipitation (Lamoureux, 1999), providing proxies for long reconstructions of hydrological variability (Lamoureux et al., 2006). Before varve thickness signals in any new location are used as paleotemperature and paleohydrological proxies, it is critical that they are calibrated for the recent period using instrumental data, whether from a nearby meteorological station or temporary measurements from process studies.

Varves have also been used to reconstruct changes in other paleoenvironmental parameters. Biogenic laminae in marine upwelling regimes reflect primary productivity, and therefore the intensity of upwelling and trade winds, in the tropical North Atlantic during the last deglaciation (Hughen et al., 1996c). Laminated sediments, and their absence, have been used to reconstruct the ventilation history of intermediate-depth waters off the coast of California (Behl and Kennett, 1996), Pakistan (Schultz et al., 1998), and northern South America (Peterson et al., 2000). These studies and others have shown that abrupt climatic shifts first seen in the high latitude North Atlantic region were in fact global in scope. Finally, varves can be used to study changes in past glacial activity and evolution of sediment source regions, as well as evolution of sedimentary basins (Lamoureux, 1999). The applications of varved sediments to geochronological and paleoenvironmental research are limitless, and will continue to grow as increasingly sophisticated methods are developed for obtaining and analyzing them.

Historical Background

The study of Quaternary vertebrates has a long-established and illustrious history and is intimately linked both to the discoveries of some of the earliest Paleolithic (old Stone Age) artifacts and to the eventual recognition of the antiquity of the human lineage. The earliest findings of fossil mammals were frequently interpreted as the remains of mythical beasts, such as dragons' (in fact, cave bear (*Ursus spelaeus*)) teeth from the caverns of central Europe, unicorns (fragments of mammoth tusk), and even the Cyclops (fossil dwarf elephant skulls from the Mediterranean islands). One of the oldest publications of Quaternary mammalian remains is that by an English writer, Mr. William Somner, who in 1669 described the finding of a 'sea monster' in 'Chartham News: A Brief Relation of Some Strange Bones There Lately Digged Up in Some Grounds of Mr. John Somner's of Canterbury.' In reality, the report recounted the discovery of three associated upper molars of a woolly rhinoceros (*Coelodonta antiquitatis*), still preserved today more than 300 years later in the Natural History Museum in London. In 1696, the finding of a fossil elephant during quarrying of travertine deposits at the site of Burgtonna in the Grand Duchy of Gotha in Germany engendered a fierce debate between Wilhelm Ernest Tentzel, historian to the dukes of Saxony, who correctly recognized the remains as 'the real bones of an Elephant, but calcined by subterraneous heat, and in a great measure petrified' and the Medical College at Gotha, which dismissed them as either the skeleton of a unicorn or naturally deposited minerals mimicking the shape of an elephant. Tentzel, despite his inspired observations, otherwise subscribed to the prevailing philosophy of the day, which invoked the biblical Deluge as the mechanism for depositing the remains. Around this time, a flint hand axe associated with the remains of an elephant was found near the Grays Inn Road in central London by a Mr. Conyers. The finds were published in 1715 by the antiquarian John Bagford, thereby furnishing the oldest known description of a Paleolithic artifact, although Bagford envisaged the implement to be the weapon of an ancient Briton, used in a fight against the Romans during the Claudian invasion of AD 43.

By the end of the 18th century, the celebrated French anatomist, Georges Cuvier, had instigated a number of comparative anatomical studies of recent and fossil vertebrates and proposed, on the basis of these, the past occurrence of fossil elephants that were similar to but clearly distinct from extant species. The recognition that extinct animals had once coexisted with ancient humans was critical to the succeeding debate concerning the ancestry of the human species. It was in the village of Hoxne in Suffolk (England) in 1797 that John Frere first established the great antiquity of the human lineage. In his famous account to the Society of Antiquaries in London, Frere reported how he had witnessed the discovery of 'weapons of war, fabricated and used by a people who had not the use of metals' (Frere, 1800). The flint hand axes that Frere had observed in the Hoxne brick

pits were associated with fragments of wood and with 'some extraordinary bones, particularly a jawbone of enormous size, of some unknown animal, with the teeth remaining in it.' The significance of Frere's report lay in his perception of the stratigraphical relationship of the deposits overlying the hand axes to the present-day topography of the Waveney valley, with the inevitable conclusion that their deposition must relate to 'a very remote period indeed; even beyond that of the present world.' Unfortunately, his inspired observations were ignored until the 1850 s, when the debate over the alleged association of flint implements with extinct animals and the question of human antiquity was reopened. Taxonomic studies nevertheless continued with the formal naming by Blumenbach in 1799 of two of the best recognized Pleistocene mammals, the woolly mammoth (*Mammuthus primigenius*) and the woolly rhinoceros.

Serious paleontological studies date back to the 19th century, such as the investigations conducted by the Reverend William Buckland, Reader in Mineralogy at Corpus Christi, Oxford (England), and later Dean of Westminster. Buckland correctly recognized that the assemblage of mammalian bones from Kirkdale Cave in North Yorkshire, which included many extinct forms and species no longer native to Britain, had been accumulated by spotted hyenas (*Crocota crocuta*). In his *Reliquiae Diluvianae* of 1823, Buckland assigned the period when the animals had been present in Britain to a time pre-dating the biblical Flood. Later, Buckland embraced the 'glacial theory' to explain geological phenomena formerly attributed to the Flood but steadfastly refused to believe that early humans had been around at the same time as these fossil mammals. A substantial breakthrough on this front was made in the 1830 s with the commencement of excavations at Kent's Cavern and Brixham Cave, both near Torquay in the southwest of England. The excavators, William Pengelly and colleagues, unequivocally demonstrated that flint artifacts had been found in association with the remains of woolly mammoth, lion (*Panthera leo*), and other animals from beneath an unbroken stalagmitic floor (Pengelly et al., 1873). In 1859, reports of exciting new finds from the Somme valley in northern France led the geologist Joseph Prestwich and the antiquarian Sir John Evans to visit the celebrated sites around Abbeville, from where they returned fully convinced that Paleolithic flint tools were indeed contemporary with an extinct fauna. Nearly 60 years after Frere's observations were so widely ignored, Prestwich and Evans revisited Hoxne to confirm his findings, thereby paving the way for a new era in Quaternary vertebrate paleontological research.

Distribution of Quaternary Vertebrate Remains

One of the reasons that vertebrates are so useful in Quaternary studies is that they make robust fossils and are found in an extremely wide range of depositional environments. Although the soft tissues, such as hair, keratin (which forms horns and

claws), and internal organs, are only found under exceptional circumstances, bones and teeth are both remarkably durable and readily identifiable to species level in the majority of cases.

One of the most common sedimentary contexts for recovering vertebrate fossils is from fluvial and estuarine deposits laid down along former river courses. These represent a combination of autochthonous remains of, for example, fish and

amphibians that would have been living in the water body and allochthonous remains of other animals, principally nonaquatic mammals and birds, that may have died nearby on the floodplain and been incorporated through overbank flooding or that may have become mired at the water's edge, been hunted there, or even drowned in the water (Figure 1). Although the fluvial record is a global one, arguably some of the

Figure 1 Part of the excavated area of the early Pleistocene Lower Fluvial Sands at Untermaßfeld (Germany) showing a floodwater accumulation including remains of bison (*Bison menneri*), comb-antlered deer (*Eucladoceros giulii*), ancient fallow deer (*Cervus* s.l. *nestii valloinetensis*), hippopotamus (*Hippopotamus amphibius antiquus*), Etruscan rhinoceros (*Stephanorhinus etruscus*), short-faced hyena (*Pachycrocuta brevirostris*), and bear (*Ursus rodei*). best sequences come from southern and western Europe, where stratified river terrace sequences preserve a remarkable succession of cold- and temperate-climate assemblages covering much of the Pleistocene. Notable examples include the Tiber (Italy), the Rhine (Germany), the Somme (France), the Maas (The Netherlands), and the Thames (England). Although some fluvial exposures are naturally created through erosion (particularly coastal sections), many fossils came to light during the late 19th and early 20th centuries when quarries for the extraction of sand and gravel were opened up, thereby providing opportunities for quarrymen and interested antiquarians to collect remains. The digging of deep foundations for buildings has also exposed Pleistocene vertebrates in unusual locations—for example, the finding of fossils of last interglacial age (Marine Oxygen Isotope substage (MIS) 5e) hippopotamus (*Hippopotamus amphibius*) in former Thames deposits under Trafalgar Square in central London. Later mechanization of aggregates extraction has made it more difficult to recover the quantity of remains previously obtained, although sand and gravel pits continue to yield spectacular finds (Figure 2) wherever paleontological and archaeological research can be combined with commercial needs. At Boxgrove in West Sussex (England), the site of an extraordinarily well-preserved early middle Pleistocene landscape with a rich vertebrate fauna, Paleolithic archaeology and hominin remains came to light as the result of quarrying activities (Roberts and Parfitt, 1999). Large numbers of vertebrate fossils continue to be dredged from fluvial sites below the water table, for example, in The Netherlands and Germany, although the stratigraphical context of these specimens has evidently been lost. Associated with the fluvial record may be spring-line deposits of subaerially precipitated tufa or travertine, laid down during interglacial periods. Examples from western and central Europe have proved to be the source of very large numbers of vertebrate fossils, including highly unusual finds such as the eggs of the European pond terrapin (*Emys orbicularis*) and bird feathers and nests from Ehringsdorf (Germany).

The deposits of former lakes and sinkholes also constitute one of the major sedimentary contexts in which vertebrate fossils may be found. The importance of lacustrine environments lies in their relatively gentle depositional environment,

Figure 2 Anterior skeleton of a Last Cold Stage (MIS 3) woolly rhinoceros (*Coelodonta antiquitatis*) discovered in 2002 at Whitmoor Haye quarry, Staffordshire, UK. Photo courtesy of G. Coates, Birmingham University Field Archaeology Unit.

thereby favoring good preservation of vertebrate material, including the potential for complete or partial skeletons. Deep lake basins have played a particularly significant role in our understanding of African Pleistocene vertebrate history, as well as providing a rich source of early hominin remains and archaeology. Lakes can also be associated with large numbers of animals that have perished due to accidental death—for example, the site of Hot Springs, South Dakota (USA), where 43 late Pleistocene mammoths, mostly young males, perished.

Caves have proved to be an extremely rich source of vertebrate fossils and excellent examples are known from every continent except Antarctica. The most common type are limestone caves, formed by the percolation of acidic groundwater through cracks and along planes of weakness in the limestone, ultimately leading to the formation of often large and complex cave systems over tens of thousands of years. Other types include volcanic caves (formed during cooling of lava flows on the flanks of volcanoes and during other, more unusual, volcanic processes, such as the circular caverns created by the *nuée ardente* explosion of Mount Fantale in Ethiopia), vertical fissure caves (created by tension in hard rocks, especially in volcanic areas or where dissected hard sedimentary rocks overlie clay), and sea caves (created by wave action). Vertebrate remains commonly found within caves include a wide variety of carnivores depending on location, such as lion, leopard (*Panthera pardus*), wolf (*Canis lupus*), spotted hyena, dire wolf (*Canis dirus*), American lion (*Panthera atrox*), and thylacine (*Thylacinus cynocephalus*). These animals used the caves for denning and rearing their young, but other carnivores occupied them mainly for overwintering (e.g., the many thousands of Last Glaciation cave bears that died during hibernation in western and central Europe). In addition, the remains of carnivore prey are also found. Herbivores otherwise rarely enter caves deliberately, unless to obtain salt (as seen today, for example, on Mount Elgon in Kenya) and occasionally to seek shelter. Notable exceptions are the spectacular Cueva de Ultima Esperanza in Chile, with rich ground sloth (*Mylodon* sp.) remains and thick deposits of ground sloth dung, and Bechan Cave in Utah (USA), where abundant Columbian mammoth (*Mammuthus columbi*) dung has been found.

More commonly, a range of vertebrates including very large mammals may become preserved in caves through accidental death, principally by falling through natural shafts or pitfalls in the roof. This can lead to the buildup of large talus cones of bone beneath former openings, an excellent example of which is known from Joint Mitnor Cave in Devon (England), which includes narrow-nosed rhinoceros (*Stephanorhinus hemitoechus*) and straight-tusked elephant (*paleoloxodon antiquus*). A similar situation is known from the Naracoorte Caves in southern Australia, where extinct sthenurine kangaroos and *Zygomaturus trilobus* (an animal the size and build of a modern pygmy hippopotamus) apparently fell through a shaft in the roof. In addition, mudflows and underground streams may carry remains inside the cave from the surrounding land surface. Small mammal remains from caves include many species of bat (usually rarely recovered from open sites) and a wide range of small rodents and insectivores brought in by birds of prey and deposited in pellets under roosting spots within the cave. Taphonomic studies conducted on these small mammal remains (Andrews, 1990) reveal the presence of patterns of

differential digestion on the molars and incisors from which the predator concerned can be identified. Early humans routinely made use of caves for shelter (presumably in competition with local carnivores), for the burial of their dead, and, from the Upper Paleolithic onwards, as a focal point for cave art.

Former marine deposits now located in onshore areas have yielded remains of whales, walruses, seals, and other marine mammals, as well as turtles and fish. Important examples are known from the 'crag' sands of northwest Europe, which represent an early Pleistocene shallow sea. Occasional terrestrial mammals of contemporary age, including the mammoth *Mammuthus meridionalis* and comb-antlered deer (*Eucladoceros* spp.), are also represented, presumably washed down from the estuaries. Dredging of the sea bed can also yield surprising finds. Many thousands of specimens of Last Glaciation mammals, including woolly mammoth (*Mammuthus primigenius*), reindeer (*Rangifer tarandus*), and bison (*Bison priscus*), have been dredged by trawlers from the floor of the North Sea between The Netherlands and the United Kingdom. This area, commonly known as 'Doggerland,' formed a land bridge between the United Kingdom and the European mainland at times of lowered sea level during the Pleistocene and was inhabited by a wide range of fauna that died and became incorporated into fluvial deposits later flooded by the Holocene sea level rise.

Some of the most unusual and celebrated Pleistocene vertebrate finds are those preserved as 'mummies' in the permafrost zones of the Northern Hemisphere, in arid areas where cold, dry air has 'freeze-dried' the bodies or hot, dry conditions have desiccated them, and in places where natural petroleum seeps have preserved the remains, sometimes 'pickling' them through a combination of oils and salt. Many well-documented examples of woolly mammoth, both juvenile and adult, have come from Siberia, where they are naturally eroded out of the frozen ground by fluvial processes. On the other side of the Bering Straits, the activities of placer mining in Alaska have brought to light a range of fauna, including spectacular remains of bison and small mammals such as black-footed ferret (*Mustela nigripes*) and ground squirrel (*Spermophilus* sp.). Examples of freeze-dried remains include the aforementioned ground sloths from South America, whereas Australia has yielded a number of desiccated specimens, including the marsupial thylacine. Remarkable accumulations of Pleistocene vertebrates have come from the petroleum seeps of Rancho La Brea in downtown Los Angeles and Talara (Peru), and both mammoth and woolly rhinoceros carcasses, pickled in ozocerite, have been recovered from Starunia on the Polish-Ukrainian border. These particular circumstances provide an exceptionally valuable insight into the appearance, diet, and overall health of these animals through investigation of the soft parts of the body, such as the skin, hair, appendages (e.g., mammoths' trunks), the stomach contents, and internal parasites. In addition, they also provide material for ancient DNA analyses, thereby allowing the reconstruction of evolutionary relationships and phylogeography (Höss et al., 1996; Barnes et al., 2002).

It is important to bear in mind that a range of materials other than the physical remains of these animals can equally provide information concerning their paleobiology and

appearance. The presence of fossil trackways (ichnofossils) can reveal the past presence of certain taxa where their actual remains may not have been preserved as well as allow stature and gait to be reconstructed. Similarly, the presence of carnivores can be detected through characteristic gnawing patterns on bones, including puncture marks, striations, and bone breakage. The most dramatic signs of carnivore activity come from the spotted hyena, a notorious 'bone cruncher.' The bone fragments are later passed out of the animal and the droppings fossilize as coprolites, thereby creating another source of evidence for past presence. Signs of rodent gnawing may also be present on bones, as well as wood and nut shells. Paleolithic cave paintings and portable art also provide important information concerning the appearance and behavior of extinct Pleistocene vertebrates that will not be apparent from their fossilized bones and teeth, such as the small ears of the woolly mammoth, the coloration of wild horses (*Equus ferus*), and the apparently maneless state of Pleistocene lions.

Sampling, Excavation, and Analysis Methods

The majority of *in situ* larger vertebrate remains in unconsolidated sediments can be recovered by hand using standard paleontological and archaeological techniques. These primarily involve the excavation of the material and the recording of its position in three dimensions (with an electronic distance meter, theodolite, or similar) and, where appropriate, on a hand-drawn scaled plan to show orientation. On Paleolithic sites, where a high level of detail may be required concerning the relationship of vertebrate remains to the archaeology, it is common practice to instigate a grid system (usually 0.5×0.5 m or larger) for excavation and recording purposes. Each square can then be excavated in 0.1-m deep spits (layers) and a proportion of the excavated spoil dry-sieved (with a 1- or 2-mm mesh) to recover any small remains that may have been missed by the excavator. Most remains can be easily exposed using a standard pointing trowel, although care should be taken when nearing the bone to switch to a wooden or plastic implement (a clay modeling tool is ideal) so as not to scratch or damage the surface. More friable material may require consolidation *in situ* (frequently involving the application of a damp tissue paper 'barrier' followed by quick-hardening plaster strips) and lifting as a block for later careful excavation in the laboratory. Better preserved material can normally be lifted, bagged, and subsequently cleaned with warm water and a soft brush prior to being allowed to dry out slowly (never in direct sunlight). Vertebrate remains found in consolidated cave deposits such as breccias usually require patient and time-consuming exposure by expert preparators using compressed air drills and other equipment. Full records of any conservation steps taken should be kept. Specialist conservation advice should be sought, as required, from appropriate authorities prior to the application of any consolidants or preservatives because these can impact later dating or chemical studies. Much late 19th and early 20th century material has been rendered useless for radiocarbon dating through the routine soaking of bones in a fishbone-derived glue that was in vogue as a consolidant.

In addition to the recovery of larger vertebrate material by hand, it is now standard practice to take bulk samples of

sediment to be wet-sieved (screened) for the extraction of microvertebrate remains. This practice has only become widespread since the 1970 s but has revolutionized paleontological studies by allowing the collection of small vertebrate fossils that are particularly useful for paleoecological and biostratigraphical studies. Samples can be taken from any suitable exposed face and would normally consist of a series of column samples from the base to the top so that any change upward through the sequence can be identified. Additional samples can then be taken from particularly fossiliferous horizons. The size of an individual sample will vary depending on the extent and nature of the sediments under investigation, but a minimum of 10 L of sediment (10–20 kg) is recommended for each. Clay-rich samples may require air-drying to weaken the hydrophilic bond of the clay particles prior to sieving in order to permit easier disaggregation of the sediment. Sediment should be wet-sieved using a 500- μm mesh, either using a handheld sieve and any convenient water source or a bespoke sieving machine, usually consisting of a large tank with a lid on the underside of which are fixed oscillating sprinklers that gently disaggregate the sediment. Once the residue is clean, it can be dried and then sorted under a low-power ($10\times$) binocular microscope in order to extract small vertebrates (teeth, bones, and bone fragments), invertebrates (if rare in the sample), and microdebitage.

Identification of vertebrate remains is carried out using keys, drawings, and comparative material (often museum collections). In addition to morphological analyses, standard metrical analyses are undertaken. These can be applied to a variety of questions, including identification problems, the recognition of sexual dimorphism, and examination of the range of natural variation within and between populations. A relatively new area of analysis is the application of geometric morphometrics to groups as diverse as microtine rodents, pigs, and horses. This involves the digital imaging of specimens and the establishment of 'landmarks' and outlines, which are then subjected to shape analysis. This permits the recognition of discrete differences in shape between populations that would not normally be revealed by standard metrical analyses. This has proved useful in identifying the area of origin of particular species and in tracking movements of different populations through time (Bignon et al., 2005; Larson et al., 2005).

Of critical importance to any fossil study is an understanding of the taphonomy (literally the 'laws of burial') of the assemblage under consideration. It is only through detailed and frequently painstaking paleontological study that the habits and lifestyles of former animal communities can be reconstructed. Understanding the biases inherent in the fossil record is therefore vital. An example of the importance of taphonomic analysis was highlighted by Brain (1981), who demonstrated that numerous South African assemblages formerly attributed to the hunting activities of *Australopithecus africanus* were in fact accumulated by carnivores. Moreover, it became apparent that the australopithecines were frequently featured as prey items (the 'hunted' as opposed to the 'hunters'). In order to understand the formation of an assemblage, it is necessary to understand the cause of death and the sequence of events that has influenced the transition from a living organism to a fossil. In vertebrates, death is usually caused by one of the following: predation, accident, senility,

starvation, or dehydration. These processes will differentially prejudice the amount and condition of material entering the sedimentary records since, for example, the victims of predation are less likely to be preserved as fossils than animals that die by accident (e.g., by falling into a cave). Biases before or during burial include: (1) varying rates of decay, dependent on temperature and invertebrate activity; (2) scavenging activities, particularly by carnivores; (3) butchery and disarticulation by early humans; (4) trampling and dispersal of the material, notably by hooved mammals; (5) the degree of exposure, weathering, and root damage on the bone surface; and (6) the effects of transportation in rivers (rolling, abrasion, and changing the orientation of bones) prior to burial. Potential biasing factors affecting an assemblage after burial include pH, recovery techniques, choice of analytical procedures, and publication decisions. Due consideration of all of these factors will greatly enhance any attempt at paleontological reconstruction.

Paleoecology

Today, most mammalian herbivores are limited to specific ecosystems, but carnivores generally have a wider distribution. During the Pleistocene, species that are today restricted largely to sub-Saharan Africa, such as lions and spotted hyenas, were found in cold and warm stages alike. Nevertheless, since most Pleistocene mammals and birds are still extant or have close relatives living today, extrapolation from the comparative anatomy and habitat preferences of modern species can be used to reconstruct past environments with reasonable confidence. Particular species associations may therefore be indicative, for example, of deciduous woodland, slow-moving water, or steppe grassland, although it is important to remember that the climatic oscillations of the Pleistocene may have disrupted communities, leading to the existence of 'disharmonious' populations that contained a mixture of species that are today native, exotic, or even extinct in a given area. However, as warm-blooded organisms, mammals and birds are more able to maintain a constant temperature against a climatic gradient than cold-blooded organisms, such as reptiles, amphibians, and fish. The latter are thus much more sensitive to temperature for basic survival and, particularly, for breeding. Accordingly, the past appearance in Britain of 'exotic' reptiles such as the European pond terrapin (Figure 3), now found only in southern and eastern Europe, is indicative of higher mean summer temperatures during previous interglacials.

Paleobiogeography

Although today, human activity has disrupted and excluded many vertebrates from existing in certain regions, the repeated patterns of climatic change during the Pleistocene also caused a change in the distributions of many vertebrate taxa. Not only did the growth and decay of glaciers cause species to move in and out of regions affected by these processes but also the changes in global ice volume had a direct effect on sea level by dictating the total land surface available for colonization and alternately opening and closing land bridges between land masses. One of the best known examples of such a land bridge,

Figure 3 Modern European distribution of the European pond terrapin (*Emys orbicularis*). From Arnold EN and Burton JA (1980) *A Field Guide to the Reptiles and Amphibians of Britain and Europe*. London: Collins.

critical to vertebrate migration, was the extensive high-latitude land connection between Asia and North America, known as the Bering land bridge, which permitted large-scale faunal interchange and provided the original route for human expansion into the Americas. Other temporary land bridges to islands allowed the immigration of certain species that then became isolated once sea level rose again. This had a striking effect on some of the largest mammals, causing them to become dwarfed in order to cope with reduced vegetational availability, whereas the smallest animals were able to expand in size because of a lack of predators. Examples of dwarf elephants and hippopotamuses are known from various islands in the Mediterranean, including Cyprus and Malta (Figure 4), whereas small-sized mammoths are known from the California Channel Islands off the west coast of the United States and Wrangel Island in northeastern Siberia. Regarding small mammals, examples of 'giant' dormice, shrews, and hedgehogs are known from the Mediterranean. Another very important factor influencing Quaternary vertebrate distribution has been the periodic expansion, movement, and contraction of areas of moderate to extreme aridity since the presence of water is critical for sustaining life. This is clearly seen in the dramatic dispersal undertaken by the saiga antelope (*Saiga tatarica*), which today inhabits the steppes and semidesert regions of southeastern Europe and Central Asia but during the Late Glacial suddenly expanded its range from southwestern Britain to Alaska, perhaps in response to a one-off pulse of exceptional aridity.

Many species therefore underwent considerable distributional shifts during the Quaternary. This is particularly evident with European fallow deer (*Dama dama*), which experienced

Figure 4 'Family group' of reconstructed individuals from Spinagallo Cave, Sicily, on display at the University of Rome (Dr T. Kotsakis as scale).

extensive expansion and contraction of its range, retreating back to its core area in the Mediterranean during cold stages and expanding throughout northwest Europe during interglacials. By tracking a preferred environment and thus maintaining a constant habitat, a species may avoid the need for evolutionary modification. However, changes in distribution (particularly contraction of the range) will often result in widespread selective mortality. This may act as a trigger for adaptive evolution as animals attempt to cope with new conditions, or it may lead to fragmentation of the population and subsequently allopatric speciation. The potential of mitochondrial DNA studies for identifying areas of glacial refugia and reconstructing phylogeographic patterns of dispersal has been highlighted by Hewitt (2000).

Biostratigraphy

One of the major advantages that vertebrates, notably mammals, have over other biological proxies concerns their applicability for the relative dating of Quaternary deposits through features such as assemblage composition, size change, origination and extinction first appearance and last appearance datums (FADs and LADs), and the significant patterns of morphological evolution, often quantifiable, that are observable in many lineages (Lister, 1992). The polar ice masses are known to have undergone major fluctuations in extent for millions of years, but it is only during the Quaternary that there was a significant mammalian response to these changes. Faunal turnover was therefore greater during the Quaternary because extinctions, immigrations, and evolutionary changes were both precipitated and magnified by these climatic changes. Because mammals can rapidly disperse into new areas and are readily preserved in a wide range of depositional environments, they are ideal for correlating different sorts of deposits over wide geographical areas. Along with these studies must be a rigorous approach to the stratigraphical and paleoenvironmental reconstruction of each site and an understanding of the taphonomy of individual assemblages. However, the replication of particular faunal groupings and identification of age-significant morphotypes at numerous sites can lead to the establishment

of credible and testable biostratigraphical frameworks, into which new assemblages may be slotted.

A number of different biochronological schemes spanning the entirety of the Pleistocene are in operation in Europe, based on land mammal ages or mammal assemblage zones. These are paralleled in North America, South America, and the Far East, although with a substantially lower degree of resolution. Formal biochronological zones in Africa and Australia have yet to be defined. Some of the most powerful evidence for the identification and correlation of different climatic episodes within Europe has come from mammalian assemblages from long fluvial sequences, such as the Tiber in Italy (Gliozzi et al., 1997), the Somme and Seine in France (Auguste, 1995), the Wipper and Neckar in Germany (Schreve and Bridgland, 2002), and the Thames in the United Kingdom (Schreve, 2001; Figure 5). These have enabled the linking of biological and lithostratigraphical evidence to create chronological frameworks that are applicable over wide areas.

The first appearance of key genera or species is of particular significance, with notable origination and dispersal events in the late Pliocene–early Pleistocene of the Canidae (Old World dogs), the genus *Mammuthus* and voles of the genus *Microtus* with unrooted (permanently growing) molars. LADs can be more difficult to establish since finds of younger age can potentially be made in the future but they are most easily recognized at the marginal areas of a species' range (e.g., the British Isles) since taxa will persist longer in the source area from where they originally dispersed. An example from Britain is the replacement of the cave bear by the brown bear (*Ursus arctos*) in the late middle Pleistocene (MIS 9; Schreve, 2001),

even though the former persisted on the continent until the end of the Pleistocene. Nevertheless, it is clear that events such as glaciations, in particular, had the potential to cause a suite of extinctions over a wide area. In addition to the origination of new species, many mammalian lineages display cladogenetic speciation (i.e., change within a lineage, without the need for geographical separation). Well-known case studies exist for the elk (moose) (Lister, 1993), mammoth (Lister and Sher, 2001), and water vole (Maul et al., 1998) lineages, with a succession of 'chronospecies' described for each. In combination, the evidence from evolutionary change within different vertebrate lineages, FADs and LADs, size change, and assemblage composition can provide a robust relative dating framework for time periods that are beyond the reach of radiocarbon dating and for contexts in which suitable materials for other absolute dating techniques may be absent.

Interactions with Hominins and Extinctions

In addition to contributing to a wider paleoenvironmental and dating context at Paleolithic archaeological sites, the final area of significance to Quaternary vertebrate studies relates to their interaction with contemporary early humans. The nature of such interactions, ranging from subsistence-related issues such as identifying predation by hominins on mammals (and vice versa) to the role of vertebrates in the parietal and portable art of *Homo sapiens*, the responsibility of humans in the late Pleistocene extinction of the megafauna, and the subsequent domestication of key mammals, is summarized elsewhere in this encyclopedia.

Introduction

The Plio–Pleistocene Transition and Biochronology

Following recent revision, the Plio–Pleistocene boundary is now dated to 2.6 Ma (Gibbard et al., 2010). Understanding the early Pleistocene vertebrate record is impossible without taking into account the late Pliocene events that influenced and characterized the composition of early Pleistocene land vertebrate communities.

Vertebrate paleontologists are used to subdividing geological time by using biochronological scales based on evolutionary stage and dispersal events. Two different biochronological scales exist for the late Pliocene–early Pleistocene in Europe, one based on micromammals that spans the late Villanyan to the Biharian and the other based on large mammals, which extends from the middle Villafranchian to the early Galerian. These ‘mammal ages’ have been further subdivided into faunal units on the basis of bio-events that produced changes in the composition of the assemblages. Similar biochronologic units are used in different continents (Figure 1): in North America, the Irvingtonian; in South America, the Uquian and the early Ensenadian; in China, the Nihewanian cover the latest Pliocene and early Pleistocene. In Australia the succession of faunal units (although not yet well defined) is outlined in Woodburne et al., (1984), while in Africa formal biochronological scales or units based on mammals have also not yet been defined (Lindsay et al., 1990).

A special mention must be made of the large-mammal age Villafranchian, due to its extensive use, especially in European literature. The term Villafranchian, proposed by Pareto in 1865, was originally considered to represent the youngest part of the continental Pliocene. In 1916, Gignoux proposed a correlation of this stage with his marine Calabrian, assumed to represent the late Pliocene. In 1948, at the 18th International Geological Congress, it was agreed to place the Calabrian at the base of the Pleistocene. Consequently, the Villafranchian was also considered to represent the earliest stage of the continental Pleistocene. Some authors (Azzaroli, 1992) remarked that the many so-called Villafranchian assemblages are neither homogeneous nor strictly contemporary. The chronological sub-division of the Villafranchian was extensively discussed during two meetings in 1975 and 1976 (Azzaroli, 1977; Alberdi and Aguirre, 1977). As a result, a number of faunal units were recognized within the Villafranchian, the oldest three belonging to the middle and late Pliocene and the others to the early Pleistocene. Within these limits the Villafranchian spans from a little over 3.0 Ma to about 1.1 Ma. During this long time interval remarkable faunal changes took place. However, the term Villafranchian has come to lose much of its intrinsic value, its name being maintained for historical reasons and for the sake of stability in nomenclature. It has no real meaning unless it is used with definite qualification, such as early, middle, and late Villafranchian, or better still with the indication of a definite faunal unit (Azzaroli, 1992).

Figure 1 Schematic correlation chart of Geochronology and Mammal Biochronology Units according to: (1) Fejfar & Heinrich (in Lindsay et al., 1990); (2) Gliozzi et al. (1997); (3) Gabunia et al. (2000); (4) Li et al. (1984); (5) Cione and Tonni (1995); (6) Marshall et al. (1984).

Early Pleistocene Case Histories

The Old World Canidae (genus *Canis*)

In a pioneering paper, Azzaroli (1983) defined the arrival in Western Europe of the first representative of the genus *Canis* 'sensu stricto' as the 'wolf event'. This event, in the original view of Azzaroli, defined the beginning of the late Villafranchian (latest Pliocene–early Pleistocene), represented by the so-called Olivola Faunal Unit.

The evolutionary history of the genus *Canis* and its dispersal across North America and the Old World reveal a much more complex pattern of dispersals and evolution of this lineage that is still obscure in several aspects. The center of origin and evolution of dogs is North America from where, across Beringia, dogs repeatedly spread into Eurasia and Africa. The first event of canid dispersal occurred in the late Miocene (Hemphillian mammal age in North America, Turolian mammal age in Europe), with forms attributable to the primitive genus *Eucyon*. Species belonging to this genus are then found, albeit rarely, across the Old World until the late Pliocene.

The earliest known representative of *Canis* 'sensu stricto' occurs in North America, in late Hemphillian deposits, about 5.5 Ma. The initial dispersal across Beringia of the genus *Canis* into the Old World occurred around 3.0 Ma. The occurrence of both

Museo di Storia Naturale (Sezione Geologia e Paleontologia), Università Firenze. Scale bar 20 cm approx. Photo: L Rook.

Canis cf. *etruscus* (the Etruscan wolf) and *Canis* cf. *arnensis* (the Tuscan coyote-like dog) are reported in deposits of this age in China. The radiation of canids in Eastern Europe, the 'wolf event', approximates with a major extinction event among carnivores, such as the raccoon-dog *Nyctereutes megamastoides* and the cursorial hyaenid *Chasmaporthetes*. The 'wolf event', one of the major faunal renewals marking the Plio–Pleistocene transition, is characterized by the appearance *Canis etruscus* (Figure 2). The event is rapidly followed in Western Europe by other arrivals, such as two other large canid species, *Canis arnensis* (Figure 2) and the primitive wild dog *Lycaon falconeri* (Figure 3), as well as by the large scavenging hyaena *Pachycrocuta brevirostris*. This carnivore guild survived over most of Eurasia for more than 1 Ma throughout the entire early Pleistocene (Rook and Torre, 1996; Martínez-Navarro and Rook, 2003).

From the Iberian peninsula to the Caucasus, a number of latest Pliocene and early Pleistocene localities provide an extensive documentation of the canid record, including Spain (Venta Micena), Italy (Poggio Rosso and Pirro Nord), Greece (Apollonia-1 and Gerakarou), Germany (Untermassfeld), and Georgia (Dmanisi).

Some of these localities (Poggio Rosso, Untermassfeld, Dmanisi) are providing an unusually abundant record that will allow a firm base to direct future research in developing studies, such as analysis of population structure and intra- and inter-specific variability.

Villafranchian Proboscideans and the Early Dispersal of Elephants

A considerable turnover in the proboscidean fauna of Eurasia took place during the Pliocene, with the local extinction of the Deinotheriidae (deinotheres survived in Africa until the early

Figure 3 *Lycaon falconeri* from Fan Tsun (Taiku, China). Skull and mandible, cast kept in the Museo di Storia Naturale (Sezione Geologia e Paleontologia), Università di Firenze; original housed in the American Museum of Natural History (New York). Scale bar represents 5 cm. Photo: L Rook.

Pleistocene), Mammutidae (*Mammuth* was present in North America until the late Pleistocene), and Gomphotheriidae (last recorded in South America in the early Holocene) and the rise of stegodonts (Stegodontidae) and modern elephants (Elephantinae). From their center of origin and diversification in Africa during the late Miocene (Shoshani and Tassy, 2005), elephants migrated into Eurasia and, in the case of mammoths, also to North America in a series of dispersal events encompassing the Pliocene and early Pleistocene. The migration of elephants out of Africa, and especially the incursion of species into Europe, have been linked to major climatic changes that had a profound impact on the evolution of Eurasian local faunas.

The earliest record of elephants in Eurasia is in early Villafranchian (middle Pliocene) deposits of the Dacic Basin (Romania), Bethlehem (Israel), the Siwaliks (India), and the Yushe Basin (China), dated between 3.5 and 3.0 Ma (Lister et al., 2004). The material from Romania has been referred to a primitive mammoth species, *Mammuthus rumanus*, to which the Chinese finds may belong, whereas the other Asian specimens represent *Elephas planifrons*, an early form of the extant Asian elephant lineage. Although the precise details of the initial radiation of elephants in Eurasia are not entirely clear, present evidence suggests that the migration of *Mammuthus* and *Elephas* out of Africa could be part of a single middle Pliocene dispersal event. This event broadly coincides with the first Northern Hemisphere glaciation at ca. 3.2 Ma that represents a major climatic change that might have triggered the Ruscinian/Villafranchian faunal transition in Europe.

After its arrival, *Elephas* dispersed throughout southern Asia, including the Indonesian archipelago. A species close to *E. planifrons* entered South Sulawesi in the middle to late Pliocene (Walanae Fauna), giving origin to an endemic small-sized form, *E. celebensis*, characterized by the presence of mandibular tusks in males. During the early/middle Pleistocene transition, *Elephas* dispersed to Java, where it is represented by *E. hysudrindicus*, a form that is dentally very close to the living Asian elephant.

Mammuthus reached a much wider geographic distribution than *Elephas* in Eurasia, which could be related to its adaptation to a more open, grassy landscape. Although *Mammuthus* is already known in Eastern Europe and Asia at around 3.2 Ma, it is not recorded in Western Europe until ca. 2.7–2.3 Ma. The dispersal of *Mammuthus* toward Western Europe marks an important faunal turnover, the so-called Elephant-*Equus*

Figure 4 *Mammuthus* cf. *rumanus* from Montopoli, Lower Valdarno (Italy, early Villafranchian). Partial skull (maxillary and premaxillary) with M3. Scale bar represents 10 cm. Museo di Storia Naturale (Sezione Geologia e Paleontologia), Università di Firenze. Photo: L Rook.

event, characterized by the extinction of warm-loving, forest-dwelling mammalian species and the entry of open habitat taxa such as the mammoth and the horse (Azzaroli, 1983). This faunal event is coeval with the global climatic deterioration that occurred at the middle to late Pliocene transition at ca. 2.6 Ma. Early records of *Mammuthus* in Western Europe are at Montopoli (Italy) and the Red Crag (England), where *M. rumanus*, or a closely similar taxon, is represented (Figure 4). *M. rumanus* is replaced in younger deposits in Eurasia by *M. meridionalis*, one of the best-known Pliocene–Pleistocene elephants (Palombo and Ferretti, 2005; Lister and van Essen, 2005). This species is well represented in the latest Pliocene to early Pleistocene deposits from Central Italy (e.g., Upper Valdarno, Pietrafitta, Scoppito), where several complete skeletons have been found (Figure 5).

Mammuthus was also the sole elephant taxon to reach North America through Beringia. The first occurrence of *Mammuthus* in North America is at the Pliocene–Pleistocene transition, and characterizes the beginning of the Irvingtonian mammal age (Agenbroad, 2005). At present, the specific identity of this first American mammoth remains unclear, though it has commonly been considered close to *M. meridionalis*. Mammoths failed to colonize South America, although it was reached by gomphotheres during the Great American Biotic Interchange. It has been hypothesized that tropical Central America acted as an ecological barrier to the southward dispersal of grassland-adapted mammoths (Prado et al., 2005).

At the end of the late Villafranchian (early Pleistocene) elephants reached their most widespread distribution since their initial radiation in the Pliocene, becoming a characteristic component of the Quaternary fauna.

The Voles (*Microtus s.l.*) Radiation

The latest Pliocene–early Pleistocene period records an important event in the history of Northern Hemisphere mammal assemblages, that is the dispersal of modern voles with continuously growing teeth, referred to the genus *Microtus* (family Arvicolidae, subfamily Arvicolinae). This genus is

Figure 5 *Mammuthus meridionalis* from Borro al Quercio, Upper Valdarno (Italy, late Villafranchian). Skeleton of an old male individual. Museo di Storia Naturale (Sezione Geologia e Paleontologia), Università di Firenze. Photo: L. Rook.

the most diverse within the arvicolids, with many subgenera, species, and subspecies and with a wide Holarctic geographic distribution.

Voles are useful paleoecological, paleoclimatic, and paleogeographic indicators. They are common in fossiliferous deposits, where they usually occur in the form of highly resistant isolated teeth or dentitions, often derived from pellets regurgitated by birds of prey.

Dental morphology is used as the main taxonomic criterion for the classification of fossil species. The most variable, and therefore most useful anatomical structure in vole evolution, is the first lower molar (M_1). Paleontologists have created a classification based entirely on the characters of this tooth, with additional reference to other teeth such as the upper third molar (M^3). The evolution of this group is characterized by a gradual complication of the occlusal surface of the molars, with an increase in the length of the anterior part of the tooth (the so-called *anteroconid complex*) due to the addition of new elements, and also by changes in the relative thickness of the enamel walls. Many studies are focused on the Pleistocene radiation of these rodents, which are ideal subjects through which to examine various hypotheses of evolutionary tempo and mode (Martin, 1998; Chalain et al., 1999).

The primitive forms of rootless voles dispersed around 2 Ma throughout Eurasia and are grouped in the genus *Allophaiomys*, which is considered both as a subgenus of *Microtus*, and as a separate genus. However, recent findings of *Allophaiomys* from China trace the origin of this lineage back to 2.3–2.4 Ma (Zheng and Zhang, 2000). The name *Allophaiomys* was coined by Kormos (1932), who recognized the similarity of these fossil dentitions to those of the recent *Phaiomys* from Southeast Asia.

Allophaiomys is considered as a transitional form between Pliocene voles of the rooted genus *Mimomys* (the species *Mimomys tornensis* being the most likely ancestor to *Allophaiomys*) and recent representatives of *Microtus* 'sensu lato' (e.g., *Terricola*, *Stenocranius*, *Pallasinus*, etc. in Eurasia, *Pedomys* and *Pitymys*, etc. in North America). The change from a Pliocene fauna dominated by rooted voles to Pleistocene faunas dominated by rootless voles was interpreted as the result of increasing aridity during the Pliocene, which modified the vegetation and induced the adaptation of these rodents to feed on more abrasive food.

Allophaiomys deucalion is the first species seen in the fossil record, with a wide geographic range across Eurasia. It is reported from Romania, Poland, Turkey and Russia (see Hir, (1998), and from China (Cai and Li, 2004). *A. deucalion* probably dispersed towards North America through Beringia, as suggested by the occurrence of species with a primitive dental condition, for example, the extinct *Microtus cumberlandensis* (Martin, 1998).

The most successful radiation of *Allophaiomys* included the descendant of *A. deucalion*, *A. pliocaenicus*, which appeared in the early Biharian and quickly developed a Holarctic distribution (Figure 6). In North America, the forms derived from *A. pliocaenicus* evolved independently from the Eurasian species, with cases of parallel evolution with the Eurasian forms, as subgenera *Pitymys* and *Terricola*, in North America and Eurasia respectively.

During the late Biharian, in the late early Pleistocene, many sites document the appearance of more progressive forms of rootless Arvicolini. An important contribution to the knowledge of this phase of vole evolution comes from the assemblage found in the lower-middle levels at the Spanish sites of Atapuerca (Cuenca-Bescós et al., 1999), which record the Bruhnes-Matuyama boundary. Within these deposits is documented the radiation of *Microtus* 'sensu lato', with the presence of early representatives of lineages that ultimately led to modern forms, for example, *Stenocranius gregaloides*, *Iberomys huescarensis*, *Terricola arvalidens*.

Other sites in Europe, with a similar chronological level as Atapuerca, bear diverse *Microtus* 'sensu lato' faunas, which include Rifreddo (Italy), Mahlis (Germany), Unéč (Czech Republic), Kozi Grzbiet (Poland), Kovesvarad (Hungary), Karai Dubina and Shamin (Russia) (see papers in 'Quaternary International', volume 131, 2005).

An Overview on the Early Pleistocene Herpetofauna

The early Pleistocene amphibian and reptile faunas are not uniformly well-known at present. Even disregarding the bias due to the skewed geographic distribution of fossil-bearing sediments of Pleistocene age, striking differences occur

Figure 6 Primitive *Allophaiomys* dentitions from the Betsia complex type locality (Romania). (a) *Allophaiomys deucalion* holotype, occlusal view of right M_1 ; (b) *A. pliocaenicus* holotype, occlusal view of left lower molar series. Redrawn from Hír (1998). Scale bar represents 1 mm.

between the information available for the well-known herpetofaunas of Europe and North America (and to some extent also Australia) and for those largely unexplored from most of Asia and Africa. The former group is represented by a considerable number of localities and taxa corresponding to several 'time slices' of early Pleistocene age, while the latter is usually represented by comparatively few sporadic findings or by localities that have yielded hominoid and hominid remains.

Given such a disparity, definitive general conclusions cannot be built on a solid dataset and only some common trends can be tentatively reported.

The most remarkable characteristic of the early Pleistocene herpetofaunas is their modernity. Although several modern taxa (genera and even species) go back to the Neogene, it is with the onset of the early Pleistocene that the herpetofaunal assemblages become almost entirely composed of modern taxa. Holman (1998 and references therein), reviewing the rich Pleistocene record of North American and European amphibians and reptiles, concluded that Pleistocene extinctions are limited to a few isolated cases (for the rest of the planet, see datasets in 'Handbuch der Paläoherpetologie' volumes).

No families appear to go extinct in North America and only one extinct amphibian family (Paleobatrachidae) and one extinct genus (*Latonia*) inhabited Europe during the early Pleistocene (the only two ascertained herpetological extinctions at supra-specific rank in Europe during the whole of the Quaternary).

Even if a few extinct taxa have not yet been detected in the fossil record of some morphologically homogeneous cryptic taxa (e.g., ranid frogs, lacertid lizards, colubrid snakes), such stability sharply contrasts with the high turnover rate in mammals and birds during the Quaternary. The possible reasons for such disparity have been discussed by Holman (1998), who suggested that the apparent stability of the herpetofaunas could be related to low metabolic rates, reproductive strategies, and food-web relationships. Such stability could also be

related to the ability to bypass climatic stress by hibernation and estivation, to adapt to climatic and vegetation changes, to exploit ephemeral and unstable habitats, and to survive for generations in sub-optimal conditions, despite facing severe genetic bottlenecks.

The early Pleistocene evolutionary history of amphibians and reptiles, as indeed for the whole Quaternary, seems to be mostly characterized by range adjustments due to habitat tracking, resulting from the environmental disruptions triggered by climatic changes. Models of herpetofaunal successions have been developed for North America and Europe, since their relatively good fossil records and the climatic oscillations leading to the cyclic development of ice sheets allow, at least in some cases, patterns of dispersal or withdrawal to be established. Conversely, almost nothing can be said about the range variations of herpetofaunal taxa in tropical forests (e.g., during pluvial periods) and arid areas. This is partly because of lack of research but also because these areas are usually unsuitable for the preservation and retrieval of small vertebrates (most of the herpetofaunal species are small-sized).

As for the early Pleistocene representatives of modern taxa, the presence of large-sized and robust forms is particularly remarkable (e.g., the thick-shelled remains of the tortoise *Testudo hermanni* and the large and massive legless lizard *Pseudopus apodus* – formerly named *P. pannonicus*). In the past these were sometimes referred to as extinct taxa but they can most likely be considered as ecotypes, probably reflecting the development of particularly, but not necessarily, favorable, auto- and sinecological conditions.

The pattern depicted above has a partial but remarkable exception in the Australian herpetofauna. Probably because Australia did not experience the Plio–Pleistocene glacial–interglacial succession that characterized a large part of the world and because of its long term of isolation and peculiar faunal stock (Irrmin, 2005), the early Pleistocene Australian herpetofauna hosted, along with the modern reptilian and amphibian taxa, some peculiar, and in most cases, primitive reptiles that later died out before the end of the Epoch (Vickers-Rich et al., 1991; Molnar, 2004).

The most striking examples of these long-term survivors are represented by the mekosuchine crocodylian *Quinkana fortirostrum*, the giant horned turtle *Ninjemys* (Figure 7) or related meiolanids, the giant monitor lizard *Varanus priscus*, and the giant snake *Wonambi naracoortensis*. Worth mentioning is that *Quinkana* represents the last ziphodont crocodylian (characterized by blade-like serrated teeth) and *Wonambi* the last madtsoiid snake.

Despite some criticism concerning the 'reptilian domination' in the Australian Pleistocene, that according to Wroe (in Irrmin, 2005) underestimates the actual ecological role of marsupial carnivores, the size of *Varanus priscus* (up to about 7 m in total length and to nearly 2 tons body mass), remains unparalleled among all Australian terrestrial vertebrates and fully deserves a top place in the trophic relationships of the continental Pleistocene.

Future directions for improving our knowledge of the earlier stages of the Pleistocene herpetofauna, that is to say of the first steps of the modern herpetofaunal assemblages, should be the careful analysis of localities in Asia and Africa, as well as in Central and South America, although such study is

Figure 7 Skull of the giant horned turtle *Ninjemys oweni* from the undetermined Pleistocene of Darling Downs (Queensland, Australia). hindered by the absence of osteological information for most of the taxa that nowadays inhabit those areas.

Acknowledgments

We are deeply indebted to the editor of the Encyclopedia, and in particular to Danielle Schreve, for the opportunity to participate in the preparation of this volume. France de Lapparent de Broin (Paris) kindly allowed access to the specimen in **Figure 7**. We dedicate this contribution to our teacher, Professor Emeritus Augusto Azzaroli, for his pioneering work on early Pleistocene mammals and for his outstanding contribution to developing research and to building up two generations of vertebrate paleontologists at the University of Florence.

Early and Middle Pleistocene of Northern Eurasia

I Vislobokova, Paleontological Institute of the Russian Academy of Sciences, Moscow, Russia

A Tesakov, Geological Institute of the Russian Academy of Sciences, Moscow, Russia

© 2013 Elsevier B.V. All rights reserved.

Introduction

The best represented vertebrate records in the early and middle Pleistocene of Northern Eurasia are mammalian and they are summarized in this article. The data from Russia and neighboring countries of the former USSR are very important for the understanding of the history of Late Cenozoic biota. The territory was a prime area of origin and evolution of taxa and of dispersals of some mammals to Western Europe, Africa, North America and China, and vice versa. The configuration of Asia was close to that of the present day but differed through the periodic existence of the Bering land bridge, connecting Siberia and Alaska. The reorganization of the biota went through climatic and environmental changes; its main trends and phases are very pronounced there.

The key stages in the history of Pleistocene mammals in this territory were first recorded by Gromov (1948) who defined the faunal assemblages for Eastern Europe and named them by their type localities or regions. Regional complexes were later defined in the Caucasus, Siberia, Transbaikalia, and Central Asia. The data on the ages of the assemblages and their compositions were considerably enriched thanks to many subsequent researchers and new discoveries. In addition to large mammals, a detailed biochronology based on small mammals has appeared in the last decades. At present, early and middle Pleistocene mammal remains are known from many localities of Northern Eurasia. The age of the localities has been established by a combination of geological and paleontological methods (including the first appearance of index taxa, as well as the evolutionary levels of dominant forms and of some phyletic lineages), paleoclimatic data and correlation. Paleomagnetic data also help to distinguish more precisely the age of early Pleistocene sites, whereas the glacial–interglacial succession provides further important markers for age determination.

The beginning of the Pleistocene is currently set at ~2.6 Ma (the Gauss–Matuyama magnetic reversal), the early–middle Pleistocene boundary at ~0.78 Ma (the Brunhes–Matuyama magnetic reversal), and the middle–late Pleistocene boundary at 0.126 Ma, according to the International Commission on Stratigraphy in 2009. However, the Geological Surveys of Russia and Ukraine have until recently retained the Pliocene–Pleistocene boundary in its former position at 1.8 Ma. In 2012 the Russian Stratigraphic Committee voted to lower the base of the Quaternary to 2.58 Ma. The position of the lower boundary of the Pleistocene and its divisions have thus been repeatedly changed over the last decades and it must be appreciated that the published names of particular stratigraphical units often refer to different time slices.

The early and middle Pleistocene in Northern Eurasia currently include the following mammal assemblages: Khaprovian, 2.6–2.2 Ma; Psekupsian, 2.2–1.2 Ma; Tamanian, 1.2–0.8 Ma; Tiraspolian, 0.8–0.4 Ma; Singilian and Khasarian, 0.4–0.126 Ma.

Mammal Assemblages of Northern Eurasia

Early Pleistocene: Gelasian, Middle Villafranchian, Late Villanyian, MN17

The Khaprovian (Khapry) mammal assemblage and its analogs

This stage is well documented in the northern Black Sea region, peri-Azov area, Siberia, and Central Asia. The mammal communities superficially resembled those of modern Africa or southern Asia by the presence of proboscideans, equids, rhinoceroses, giraffids, and various antelopes, but differed considerably from them in species composition. These assemblages are characterized by the first appearance and subsequent wide distribution of the elephant *Archidiskodon gromovi* (= *A. meridionalis gromovi* in Titov, 2008, = *Mammuthus gromovi* of Lister and Sher, 2001). In contrast to Russian paleontologists, most researchers refer this species to the genus *Mammuthus*, mainly based on the tooth structure (Lister and Sher, 2001), although *Archidiskodon* is retained here. Other features of the fauna include the presence of the bear *Ursus etruscus* and the rhinoceros *Stephanorhinus* sp., the rapid diversification and wide distribution of stenonid horses, the presence of diverse canids (*Eucyon*, *Nyctereutes*, *Canis*), two saber-toothed cats *Homotherium crenatidens* and *Megantereon cultridens*, the camel *Paracamelus*, the large-sized comb-antlered deer *Eucladoceros* and the elk (= moose) *Libralces*, and other extinct forms. In Northern Eurasia, there were three paleogeographic subareas: European-Siberian, Mediterranean, and Central Asian (Vangengeim and Pevzner, 1991; Vislobokova et al., 1995) (Figure 1). The global cooling witnessed at about 2.6 Ma (indicated in the territory by the glaciations of the Caucasus and Pamir, the most ancient loess formation in Tadzhikistan, Uzbekistan, etc.) caused a decrease in humidity in temperate latitudes and in Central Asia (Dodonov, 2002), where animals adapted to open woodlands and grasslands became dominant. Some taxa have North American ancestry, immigrating during periods of low sea level prior to the start of the Pleistocene, such as the camels, *Hipparion* and *Eucyon* in the late Miocene, and *Equus*, *Canis*, and *Megantereon* in the Pliocene (Vislobokova et al., 2003). A number of thermophilous herbivores (mastodons, giraffids, and others), typical of Pliocene times, were gradually replaced by forms adapted to cooler climatic conditions and possessing more advanced herbivorous adaptations. The data on herbivorous taxa (elephants, horses, ruminant Artiodactyla, voles, etc.) are of great value for biochronology and paleoenvironmental reconstruction because their tooth structure yields clearly recognizable signals in wear patterns, hypsodonty, etc. The increase in diversity of herbivore taxa was accompanied by considerable changes in the carnivore guild.

At this time, an extensive European-Siberian part of the Palearctic was inhabited by the elephant *Archidiskodon gromovi*, the rhinoceros *Elasmotherium*, and large *Equus livenzovensis* and small *Equus* sp., together with other animals adapted to

Figure 1 Early Pleistocene paleozoogeographic subareas and main localities: (1) European-Siberian subarea; (2) Central Asian subarea; (3) Mediterranean subarea.

savanna-like conditions (the wolves of the *Canis etruscus* group, the hyena *Pliocrocuta*, the saber-toothed cat *Homotherium crenatidens*, the cheetah *Acinonyx*, the camel *Paracamelus*, the antelope *Gazellospira*, the bison-like *Leptobos*, and others), along with forest and ecotonal animals (the bear *Ursus etruscus* and the deer *Eucladoceros* and *Libralces*). Most of these mammals were found in common with those from the Middle Villafranchian faunas of Western Europe (Kahlke et al., 2011; Palombo et al., 2006). Early Villafranchian elements (the mastodon *Anancus arvernensis*, the archaic horse *Hipparion*, and giraffids) became very rare. Among the small mammals, the bank voles *Clethrionomys* made their first appearance, the water vole *Mimomys polonicus* was replaced by *M. pliocaenicus* in the Northern Black Sea area, and the pikas *Pliolagomys* and *Ochotona* and jerboas *Allactaga*, more typical of Asian faunas, were present.

Fossil remains of *Archidiskodon gromovi*, the main indicator species of the Khaprobian mammal assemblage, have been found in a number of localities in the European part of Russia (Khapry, Liventzovka, and others), in the Ukraine (Zhevakhova Gora), in the south of Western Siberia (Podpusk-Lebyazh'e), and in Central Asia (Adyrgan, Kuruksay) (Bajgusheva, 1971; Garutt and Bajgusheva, 1981; Vangengeim et al., 1988; Vislobokova, 1996, 2005; and others). *A. gromovi* has also been found in Italy (Montopoli) (Gliozzi et al., 1997).

Remains of other members of the Khaprobian assemblage are recorded from many European-Russian sites along the northern coast of the Sea of Azov and the right bank of the

Don River near Rostov-on-Don and Taganrog. They come from the lower part of the Khapry alluvium recorded in sand pits and natural outcrops. The large mammals were represented by *Anancus arvernensis alexeevae*, the horses *Hipparion moritorium*, *Equus* (*Allohippus*) *livenzovensis*, and a small *Equus* sp., the rhinoceroses *Stephanorhinus* ex gr. *megarhinus-kirchbergensis* and *Elasmotherium chaprovicum* (= *E. cf. caucasicum*), the wild boar *Sus strozzi*, the camels *Paracamelus alutensis* and *Paracamelus cf. gigas*, the deer *Cervus* (*Rusa*) *philisi*, *Eucladoceros cf. dicranios*, *Arvernoceros* sp., and *Libralces gallicus*, the giraffid *Palaeotragus* (*Yurlovia*) *priasovicus*, and the bovids *Leptobos* sp., *Gazellospira gromovae*, *Tragelaphini* gen. indet., *Gazella cf. subgutturosa*, and others (Alexeeva, 1977; Bajgusheva, 1971; Bajgusheva et al., 2001; Gromov, 1948; Titov, 2008; and others) (Figure 2). The Khapry carnivores included the raccoon-dog *Nyctereutes megamastoides*, *Canis* sp. (*C. cf. senezensis*: Sotnikova et al., 2002), the mustelids *Lutra* sp. and *Pannonictis nesti*, the medium-sized hyena *Pliocrocuta perrieri* and the dominant larger-sized short-faced hyena *Pachycrocuta brevirostris*, the felids *Lynx issiodorensis*, the saber-toothed cat *Homotherium crenatidens*, and the cheetah *Acinonyx pardinensis*. Most of these animals were inhabitants of open savannah-like landscapes, with a part of the fauna adapted more to forested or ecotonal zones (mustelids, lynx, wild boar, and deer). Among the small mammals, the archaic lagurine *Borsodia praeungarica*, the water voles *Mimomys praepliocaenicus* and *Mimomys* ex gr. *reidi*, and the primitive red-backed voles *Clethrionomys kretzoi* were also present (Tesakov, 2004).

Figure 2 *Anancus arvernensis*, C. Flerov painting exhibited in the Paleontological Museum of the Paleontological Institute, Russian Academy of Sciences (PIN) in Moscow, with PIN permission.

Figure 3 Podpusk–Lebyazh'e locality at the right bank of the Irtysh River, Western Siberia.

In the south of Western Siberia, faunal assemblages described by Vangengeim and Zazhigin have been reported from Podpusk-Lebyazh'e, from the lower part of the thick sandy alluvial deposits exposed on the right bank of the Irtysh River, south of Pavlodar (Vangengeim, 1977; Vislobokova, 1996; Figure 3). Typical members include *A. gromovi*, *S. cf. etruscus*, *Elasmotherium* sp., *Equus livenzovensis*, *Equus* sp. (small), *Paracamelus* cf. *gigas*, *Eucladoceros* sp., *Leptobos*, and the antelopes *Gazella* cf. *sinensis* and *Antilospira* cf. *gracilis* (Vislobokova, 1996). The faunal assemblage consisted mainly of forms widespread in the temperate zone of the Palearctic region (*Ursus* cf. *etruscus*, *Homotherium*, *Pachycrocuta*, and others), with some Central Asian elements (*Ochotonoides*, *Elasmotherium*, *Paracamelus*, *Antilospira* cf. *gracilis*, *Gazella* cf. *sinensis*), some of which (e.g., *Paracamelus*) reached Eastern Europe. Among the small mammals, voles with rooted dentition of the genus *Mimomys* (*M. pliocaenicus* and *M. reidi*) and *Borsodia* (*B. praeungarica-petenyii*) were predominant and *Clethrionomys* appeared for the first time in Siberia (Zazhigin, 1980). The mammalian assemblages indicate the prevalence of steppes with woodland developed along river valleys.

In northeastern Asia, the association of *Synaptomys*-like lemmings *Pliotomys* and mimomyian voles *Cromeromys* ex gr. *irtyshensis-hordijki* and smaller *Mimomys* sp. were found in the lower member of the Kutuyakh Formation at the Krestovka River in the Kolyma Lowland (Sher, 1987; Tesakov and van Kolfshoten, 2011). The assemblage is dominated by lemmings and 'Cromeromys' voles, with *Ochotona* sp. and *Mimomys* sp. being less abundant.

Several faunas of this age have been referred to the Central Asian subarea (Erbaeva and Alexeeva, 2000; Sotnikova et al., 1997; Vangengeim, 1977; Vislobokova et al., 1995). These include the Itanza fauna of Klochnevo I, II (Transbaikalia) with *Ochotona intermedia*, the ground squirrel *Spermophilus itancinicus*, *Allactaga* sp., the hamster *Cricetinus varians*, the voles *Mimomys pseudintermedius*, *Clethrionomys* sp., and 'Villanyia' klochnevi, the archaic mole rat *Prosiphneus* cf. *paringi*, the first representative of the giant deer genus *Praemegaceros* and others, as well as the Kiikbai and Andyrkan faunas (southern Kazakhstan) with *Ochotonoides complicidens*, *Mimomys pliocaenicus*, the gerbil *Meriones* cf. *meridianus*, *Equus stenonis*, the camel *Gigantocamelus longipes*, and other forms.

The fauna of Southern Tadzhikistan has affinities with the Eastern Mediterranean subarea and is characterized by a combination of Mediterranean and Central Asian forms. The rich assemblage from Kuruksay contained, along with *A. gromovi* and *Mastodontoidea* fam. et gen. indet., the baboon *Papio sushkini* (= *Paradolichopitecus sushkini*), the porcupine *Hystrix* sp., diverse carnivores including *Nyctereutes megamastoides*, eucyon 'Canis' kuruksaensis, *Ursus* cf. *etruscus*, the cursorial hyena *Chasmaporthetes lunensis kani*, *Pliocrocuta perrieri*, *Lynx* ex gr. *issidorensis*, *Acinonyx* cf. *pardinensis*, *Megantereon megantereon*, and *Homotherium crenatidens*, the rhinoceros *Stephanorhinus* sp., the horse *Equus stenonis pamirensis* (= *E. s. bactrianus*), the camel *Paracamelus praebactrianus*, the deer *Axis flerovi* and *Elaphurus eleonora*, the first representative of the giant deer genus *Sinomegaceros* (*S. tadzhikistanis*), the elk *Libralces* cf. *gallicus*, the giraffids *Sogdianotherium kuruksaense* and *Sivatherium*, and the antelopes *Gazella parasinensis*, *Protorix paralaticeps*, *Damalops palaeindicus*, *Gazellospira gromovae*, and *Antilospira* sp., amongst others (Dmitrieva, 1977; Vangengeim et al., 1988). In this region, a large number of Asian elements occurred. Animals of dry, open landscapes (*Ellobius*, *Pliocrocuta*, *Chasmaporthetes*, *Paracamelus*, *Equus*) were accompanied by forest animals (bear, lynx, monkey, the deer *Axis* and *Libralces*) and savannah inhabitants (*Sivatherium*, *Protorix*, *Damalops*, *Gazellospira*). Such a mixed composition reflected the mosaic landscapes and vertical zonality typical of mountainous regions. In Tadzhikistan, the local faunas attributed to this assemblage are known also from Obigarm, Karamaidan, Tutak, and Zil'fi localities, while faunas close to them in age were found in Kyrgyzstan (Akterek, Dzylygdykoo) (Dmitrieva and Nesmeyanov, 1982; Sotnikova et al., 1997).

The reversed polarity of the fossiliferous deposits in Khapry indicates that these sediments should be attributed to the lower part of the Matuyama Chron, together with analogous sites in Siberia and Central Asia (Podpusk-Lebyazh'e, Krestovka, Kuruksay) (Sotnikova et al., 1997; Tesakov et al., 2007; Vangengeim and Pevzner, 1991; Vangengeim et al., 1988; Vislobokova, 1996).

Late Early Pleistocene: Late Villafranchian, MN18–MQ19, = Tiglian–Menapian

Psekups mammal assemblage and its analogs

This stage is characterized by significant changes in the diversity of mammal communities (Figure 4). In Northern Eurasia, a cold-climate event around 2.2–1.9 Ma resulted in the appearance of new boreal elements, including some modern genera. In the European-Siberian subarea, *Archidiskodon gromovi* was replaced by the more progressive *A. meridionalis* (= *Mammuthus meridionalis*), close to the type of the species from the Upper Valdarno, Italy. Voles of the genus *Allophaiomys*, the giant deer *Praemegaceros*, the elk *Alces*, the large bovids of the genus *Bos* and the *Bison* (*Eobison*) – *B. (Bison)* phyletic lineage, and the musk-ox *Soergelia* first appeared in this stage.

In Psekups (Northern Ciscaucasia), *Archidiskodon meridionalis*, *Eucladoceros orientalis* (= *Psekupsoceros orientalis*, first recognized as *Cervus pliotarandoides*), *Stephanorhinus etruscus*, and *Equus stenonis* were present (Alexeeva, 1977; Gromov, 1948; Vislobokova, 1990; and others). The small mammals included *Borsodia newtoni-arankoides*, *Pitymimomys pitymyoides*, *Mimomys* cf. *pliocaenicus*, *Mimomys reidi*, and *Clethrionomys kretzoi* (Alexandrova, 1976; Tesakov, 2004). These reversed polarity deposits correspond to the Matuyama Chron, between the Reunion and Olduvai Subchrons (Tesakov, 2004; Vangengeim and Pevzner, 1991). Slightly younger assemblages from the Odessa small mammal complex contain hypsodont *Mimomys* forms (dominant *M. reidi* and *M. ex gr. savini*), the last representatives of *Borsodia*, the first occurrence of lagurines with

Figure 4 Mammal assemblages and faunas of Northern Eurasia and the main lineages.

Figure 4 (Continued)

unrooted teeth *Prolagurus* and *Lagurodon*, and *Allophaiomys deucalion* (Alexandrova, 1967; [Rekovets and Nadachowski, 1995](#); [Tesakov, 2004](#)). The Odessa assemblage is subdivided into two phases: (1) an early phase, with the remains of rootless voles *Allophaiomys deucalion* and (2) a late phase, with the first cemented rootless voles of *Prolagurus* (*P. ternopolitanus*) and *Lagurodon* (*L. arankae*) ([Markova, 1982, 2007](#)).

In the Caucasus, the Dmanisi fauna is famous for the presence of the first appearance in Eurasia of *Homo*, following dispersal from Africa. The remains of the Dmanisi hominins are attributed to the *Homo erectus* group and were found in the layers directly overlying a lava flow with a radiometric date of 1.8 ± 0.1 Ma, within the Olduvai Subchron. The fauna comprises inhabitants of dry, open area (the tortoise *Testudo*, the ostrich *Struthio*, the gerbil *Parameriones*, the pika *Ochotona*, the hamster *Cricetulus*, *A. meridionalis*, *Canis etruscus*, *Pliocrocota*

cf. perrieri, *Megantereon cultridens*, *Homotherium crenatidens*, *Palaeotragus*) and forest animals (*Bison* (*Eobison*) *georgicus*, the deer *Cervus abesalomi* and *Dama nestii*, the bear *Ursus etruscus*) ([Gabunia and Vekua, 1995](#); [Hemmer et al., 2010](#); [Vekua, 1995](#); [Vekua and Lordkipanidze, 2008](#)). The first occurrences of the 'jaguar' *Panthera onca georgica* and musk ox *Soergelia* are recorded there. The contemporaneous Palan-Tyukan fauna (Azerbaijan) includes *Canis etruscus*, *Panthera ex gr. onca gom-baszoegensis*, and *Nyctereutes megamastoides*.

In Western Siberia, *A. cf. meridionalis*, *Equus ex gr. stenonis*, *Alces sp.*, and *Gazella sp.* along with *Borsodia ex gr. petenyi-hungaricus*, and *Mimomys coelodus* are known from the Podpusk fauna (from the uppermost part of the sands in the Irtysh River Basin) ([Vislobokova, 1996](#)). In southern Kazakhstan, the Aktogai (Kopaly) locality with *Mimomys* (*Tcharynomys*) *haplo-dentatus* (bed 3) and *Allophaiomys deucalion* (bed 7) also

corresponds to this age (Sotnikova et al., 1997; Tjutkova and Kaipova, 1996).

In the Kuznetsk Depression, *Allophaiomys pliocaenicus*, *Prolagurus* ex gr. *pannonicus-posterius*, *Eolagurus argyropuloi*, *Archidiskodon* cf. *meridionalis*, and *Ovibovini* gen. indet. were found in the Mokhovo Formation, 1.8–1.2 Ma (Foronova, 2001).

In northeastern Asia, a tooth of *Archidiskodon meridionalis* was found in the Vilyuisk district, Yakutia; the find confirmed the spread of the subspecies into North America over the Bering land bridge (Dubrovo, 1990), probably at the end of the 2.9–2 Ma global sea level fall.

In Transbaikalia, the Dodogol and Zasuchino II faunas have been referred to the Central Asian subarea. In Dodogol, *Borsodia laguroformis*, *Allophaiomys* cf. *pliocaenicus*, *Prosiphneus youngi*, the first woolly rhino *Coelodonta* (of Asian origin), *Equus* ex gr. *sanmeniensis*, and others were present (Vangengeim, 1977). The revised data on the Pleistocene small mammals of the region are presented in Alexeeva et al. (2007) and Alexeeva and Erbaeva (2008).

Terminal Early Pleistocene: Early Galerian, 1.2–0.8 Ma

The time range from 1.2 to 1.1 Ma (before the Jaramillo paleomagnetic reversal) is an important boundary in the history of the biota, and is reflected in the nomenclature of stratigraphic schemes (the Villafranchian–Galerian boundary or the Early–Late Eopleistocene boundary in the scheme of the Russian Stratigraphic Committee).

Tamanian mammal assemblage and its analogs (Nogaitsky–Morozovka, = Menapien–Bavelian)

This stage is characterized by the replacement of *Archidiskodon meridionalis meridionalis* by the more advanced *A. meridionalis tamanensis*, the first appearance of the giant deer *Praemegaceros verticornis* and *Megaloceros*, the red deer *Cervus* (*Cervus*) *acoronatus*, the roe deer *Capreolus* cf. *suessenbornensis*, the broad-fronted elk *Alces latifrons*, the bison *Bison* (*Bison*), camels of the genus *Camel*, the first occurrence of the woodland elephant *Palaeoloxodon* and woodland antelopes *Tragelaphus* and *Pontoceros*, and the presence of *Paracamelus* (*P. kujalnensis*) (Alexeeva, 1977; Gromov, 1948; Vekua, 1962; Vereshchagin, 1957; and others). From the end of the early to the middle Pleistocene, true wolves attributed to the *Canis mosbachensis*–*C. variabilis* group and large hunting dogs *Lycaon lycaonoides* (= *Canis* (*Xenocyon*) *lycaonoides*) existed in Eurasia from Western Europe to Transbaikalia and China (Sotnikova and Rook, 2010).

The Tamanian mammal assemblage is based on the fauna of Synaya Balka (type locality) and Tsymbal in the Taman Peninsula. *A. meridionalis tamanensis* coexisted in the North Black Sea area with *Homotherium crenatidens*, the short-faced hyena *Pachycrocuta brevirostris*, the horse *Equus suessenbornensis*, the rhinoceroses *Stephanorhinus etruscus* and *Elasmotherium caucasicum*, and others (Alexeeva, 1977; Sotnikova and Titov, 2009; Vereshchagin, 1959; Figure 5). Vereshchagin (1957) also identified the potential impact of early hominins on some of these assemblages. And recently, stone artifacts of the Oldowan type were reported from the Synyaya Balka site by Shchelinsky et al. (2010). In the Asian part of the territory, the first reliable evidence of human activity comes from the stone tool assemblage of Kuldara (Ranov et al., 1995) dated to

Figure 5 A skeleton of *Elasmotherium* on display in the Paleontological Museum of the Paleontological Institute, the Russian Academy of Sciences (PIN), Moscow, with PIN permission.

0.8 Ma and broadly synchronous with stone tools from the Karama site in the Altai region (Derevyanko and Shunkov, 2005).

Morozovkian small mammal fauna with more derived voles *Microtus* (*Stenocranius*) *hintoni* and the pitiomyoid *Microtus* sp. are correlated with these assemblages (Alexandrova, 1976; Rekovets and Nadachowski, 1995). The small mammal fauna of this stage are also represented in the Dnieper, Dniester, and Don basins (Agadjanian, 2009; Alexandrova, 1976; Markova, 2007; Tesakov et al., 2007; Topachevsky et al., 1987; and others). The assemblages include an advanced meadow vole *Allophaiomys* (*A. pliocaenicus*) and the steppe lemmings *Prolagurus pannonicus*, *Lagurodon arankae*, and *Eolagurus argyropuloi*.

At this time, differentiation of environment sharply increased. In the Caucasus (Akhalkalaki, Georgia), the most thermophilous elements continued to exist, including *Hippopotamus georgicus*, *Equus suessenbornensis*, and *Stephanorhinus hundsheimensis*, the cave or ‘spelaeoid’ bear close to *U. deningeri*, and the first jaguar (close to *P. onca gomboszoegensis*) (Hemmer et al., 2010; Vekua, 1962, 1986). In Siberia, the diversity of musk-oxen increased. The ovibovine *Soergelia* occurred in the Razdolie assemblage (Western Siberia) with *A. meridionalis*, *Palaeoloxodon* sp., *Equus* (*Allohippus*) sp., *Bison* sp., and *Ovibovini* (Vangengeim, 1977). The remains of *Soergelia* and the oldest members of *Praeovibos* were found in the early stage of the Olyorian land mammal age (Beringia, Bering Province) (1.4–0.8 Ma) together with those of the first wolverine *Gulo minor* (= *G. cf. schlosseri*) (Sher, 1971, 1987; Sher et al., 2011; Vangengeim, 1977). These co-occurred with *Archidiskodon* sp., *Lycaon lycaonoides*, *Equus* (*Plesippus*) *verae*, *Alces* sp., *Bison* sp., and others. The northernmost finding of *Homotherium* in Asia is associated with this fauna. In Eastern Siberia, the Aldan fauna included a number of forest inhabitants (*Trogontherium* cf. *cuvieri*, *Palaeoloxodon* ex gr. *namadicus*, *Alces latifrons*, and *Microtus gregaloides*). In Transbaikalia, the Kudun (Kizhing–Kudun depression) and Zasuchino (Itanza River basin) correspond to the youngest part of the early Pleistocene and are correlated with the uppermost Matuyama Chron (Erbaeva and Alexeeva, 2000).

The oldest *Camelus* (*C. cf. knoblochi*) coexisted with the giant deer *Praemegaceros* (close to *P. verticornis*) in southern

Tadjikistan (Lakhuti locality, the uppermost part of the Matuyama) and members of diverse habitats. They included inhabitants of open, dry, and savannah-like landscapes, such as the gerbil *Meriones lacutensis* and mole vole *Ellobius lakhutensis*, *Archidiskodon* sp., *Equus* cf. *namadicus*, and *Canis* cf. *mosbachensis*, in association with a large *Lycaon*, *Pachycrocuta brevirostris*, *Homotherium* sp., the red-backed vole *Clethrionomys*, *Panthera onca gomboszoegensis*, the badger *Meles* ex gr. *meles*, and the giant deer *Sinomegaceros* sp. (Sotnikova, 1989; Sotnikova and Vislobokova, 1990). Small mammals also included white-toothed shrew *Crocidura* sp., a hamster *Cricetulus* sp., the meadow voles *Allophaiomys* sp., and *Microtus* (*Phaiomys*) *lakhutensis* (data from Zazhigin).

Faunas intermediate in age between the Tamanian and Tiraspolian faunas are known from the lower course of the Dnester River (Karai-Dubina) and in the middle Don (Petro-pavlovka) area and have been studied in detail (Agadjanian, 2009; Markova, 2007). The reversed polarity deposits contain the remains of *Prolagurus* and pitomyoid *Microtus*, the last representatives of *Allophaiomys*, and the oldest *Microtus* with five closed enamel triangles in the first lower molar.

The dispersal of mammals out of Northern Eurasia increased from about 1.2 to 1.1 Ma; *Praemegaceros verticornis* and *Soergelia* invaded Western Europe and *Homo erectus* and *Sinomegaceros* first occurred in China (Kahlke et al., 2011; Qiu, 2006).

Early Middle Pleistocene: Middle–Late Galerian, = Cromerian–Elsterian, 0.8–0.4 Ma

The early–middle Pleistocene boundary of the standard scheme corresponds to the Eopleistocene–Neopleistocene boundary of the Russian stratigraphic scheme and the Early–Middle Galerian boundary in Italy.

Tiraspolian mammal assemblages and its analogs

The considerable reorganization in the composition of mammalian communities was related to a drop in temperature at the early–middle Pleistocene boundary, with a notable increase in amplitude of climatic oscillations. Along with progressive cooling, climatic fluctuations changed from 41-ka low-amplitude cycles to a 100-ka high-amplitude cycle (Shackleton, 1995). In the Russian Plain, three periods of glaciation correspond to this stage (Pokrovka, Don, and Oka). The climatic zonation of the northern Eurasian landscape began to resemble that of the present day (Figure 6). *Archidiskodon* was replaced by the mammoth *Mammuthus trogontherii* (= *A. wüsti*) and the proportion of modern vertebrate genera sharply increased.

The representatives of the Tiraspolian mammal assemblage in southeastern Europe existed under a temperate climatic regime in a variety of landscapes, dominated by forest-steppes (Alexeeva, 1977). Kolkotova Balka (near Tiraspol) is the type

Figure 6 Zonal occurrence of mammals in the early–middle Pliocene, with some data from Markova (2006): (1) steppe; (2) forest-steppe; (3) mixed and broadleaved forests; (4) *Picea-Pinus* and *Betula* forests, with some broadleaved plants; (5) *Picea-Pinus* forests and steppe; (6) forest–tundra; (7) tundra.

locality of this assemblage. The fossil remains were found in the so-called 'Tiraspolian gravels' (fluvial deposits of the Dniester 6th terrace). Horses were represented by both caballoid (*Equus* cf. *mosbachensis*) and stenois (*E. aff. suessenbornensis*) forms. *Mammuthus trogontherii*, *Stephanorhinus etruscus* (late form), the large deer *Cervus acoronatus*, *Praemegaceros verticornis*, the fallow deer *Praedama* and *Alces latifrons*, and a short-horned bison *Bison schoetensacki* are common to both the Tiraspolian fauna and the fauna of Western Europe (Kahlke et al., 2011; Nikiforova, 1971). Two skeletons of *M. trogontherii* were found in the Kagalnik sand pit (Azov). Data on small mammal fauna represent several phases of Tiraspolian mammal assemblages (see Markova, 2007). A considerable cooling has been recognized in the southern part of European Russia at the time of the early middle Pleistocene Don glaciations, highlighted by the presence of subarctic species such as the lemmings *Lemmus* ex. gr. *Sibiricus* and *Dicrostonyx* sp. and the North Siberian vole *Microtus* ex gr. *hyperboreus* (Agadjanian, 2009).

The southward shifting of ranges, with persistence of some forms in refugia (including mountain ones), was usual during continental glaciations. Very diverse mammal faunas are known from the northern Caucasus. Most are associated with Early Paleolithic sites and stone artifacts of Acheulian type. The taxa include the macaque monkey *Macaca* cf. *sylvana*, the spotted hyena *Crocota spelaea*, diverse bears including cave bear *Ursus deningeri* (dominant), black bear *Ursus* ex gr. *thibetanus* probably related to *U. etruscus*, and the small cave bear *U. savini rossicus* (= *U. aff. spelaeus rossicus*), the cave lion *Panthera spelaea* and leopard *P. pardus*, the gray wolf *Canis lupus*, the fox *Vulpes vulpes*, *Stephanorhinus*, *Megaloceros giganteus*, *Capreolus* cf. *suessenbornensis*, *Bison* cf. *schoetensacki*, together with typical montane genera such as the ibex *Rupicapra* and the goat *Capra*.

The fauna of the late stage of the Olyorian faunal assemblage (West Bering Province) are characteristic of tundra and forest-tundra environments and cold climatic conditions similar to modern ones (Sher, 1971, 1987; Vangengeim, 1977). This fauna included the first reindeer *Rangifer*. *Alces* aff. *latifrons* and *Bison* sp. were also present in the artiodactyl community. *Rangifer* is also recorded in the early middle Pleistocene of the Kuznetsk Depression (Foronova, 2001).

In Transbaikalia, the Tologoi assemblage contained the woolly rhino *Coelodonta tologojensis*, *Equus* ex gr. *sanmeniensis*, *Cervus* ex gr. *elaphus*, *Spirocerus* cf. *peii*, and *Bison* sp. (Vangengeim, 1977). Cryogenic disturbance at the base of the deposits is associated with remains from the Zasuhino assemblages (Zasuhino 3, 1–0.78 Ma) and in Tologoi 2 beneath the Brunhes–Matuyama magnetic reversal, above the Jaramillo (Alexeeva, 2005). The fauna is characterized by a large diversity of carnivores and ungulates: *Nyctereutes* sp., *Canis variabilis*, *Lycan* cf. *lycaonoides* (= *Xenocyon lycaonoides*), *Ursus* sp., *Gulo* sp., *Pachycrocuta brevirostris*, *Homotherium* sp., the large-sized tiger *Panthera* ex gr. *tigris*, *Coelodonta tologojensis*, *Equus* ex gr. *sanmeniensis*, *Equus* ex gr. *suessenbornensis-verae*, *Alces* cf. *latifrons*, and others (Vangengeim et al., 1990). Zasuhino 3 locality also has yielded *Cervus* sp., *Megacerini* indet., *Capreolus* cf. *suessenbornensis*, *Ovibovini* indet., and *Bison* sp.

At the boundary of the early and middle Pleistocene, a prominent climatic deterioration was marked over northern and central Eurasia and many immigrants from these regions

are recorded in Western Europe. The Bering land bridge (0.8–0.011 Ma) further facilitated faunal exchanges between Northern Asia and North America.

Late Middle Pleistocene, = Aurelian, = Holsteinian–Saalian, 0.4–0.126 Ma

Singilian and Khasarian faunas and their analogs

The Singilian fauna and its analogs are related to the Likhvin interstadial (= Mindel-Riss, = Holsteinian), one of the most pronounced warm stages in the middle Pleistocene. In Eastern Europe, the Singilian faunas were represented by the straight-tusked elephant *Palaeoloxodon antiquus* and Merck's rhinoceros *Stephanorhinus kirchbergensis*. In the south of Northern Eurasia, gray wolf (*Canis lupus*), *Camelus knoblochi*, *Megaloceros giganteus*, and *Bison priscus longicornis* became widespread after the mid-middle Pleistocene (Alexeeva, 1977; Gromov, 1948). Typical small mammals include the water vole *Arvicola mosbachensis*, the yellow steppe lemming *Eolagurus luteus*, the narrow-skulled vole *Microtus gregalis*, the northern or root vole *M. oeconomus*, *Ellobius*, and the ground squirrel *Spermophilus* (Markova, 2007). In Western Siberia, *Palaeoloxodon* coexisted with *Equus* cf. *steinheimensis*, a small-sized cave bear *Ursus savini rossicus* (= *Ursus spelaeus rossicus*), and the giant deer *Megaloceros giganteus* during the contemporaneous Tobol interstadial (Vangengeim, 1977; Figure 7). From this time onward (~400 ka), the giant deer became widespread in the temperate latitudes of Eurasia, together with modern deer species (red deer *Cervus elaphus* and the reindeer *Rangifer tarandus*).

The Khasarian faunal assemblage (Dnepr glaciation) with its type locality at Cherny Yar (Volga River Basin) contained *Mammuthus trogontherii chosaricus* (ancestor of the woolly mammoth *Mammuthus primigenius*), *Panthera spelaea*, *Elasmotherium sibiricum*, the woolly rhinoceros *Coelodonta antiquitatis*, *Equus chosaricus*, *Camelus knoblochi*, the long-horned bison *Bison priscus longicornis*, *Megaloceros giganteus*, and modern genera and species, including *Cervus elaphus*, *Rangifer tarandus*, the musk-oxen *Ovibos*, the saiga antelope *Saiga*, etc., the water vole *Arvicola chosaricus*, and a diverse assemblage of steppe-adapted small mammals (Alexandrova, 1976; Dubrovo, 1985; Gromov, 1948). The fauna existed in the colder and drier

Figure 7 *Megaloceros giganteus*, C. Flerov's painting exhibited in the Paleontological Museum of the Paleontological Institute, Russian Academy of Sciences (PIN), Moscow, with PIN permission.

climate of the periglacial forest-steppe along the southern margin of the continental Dnieper glaciation (Riss, RI) (Vangengeim, 1977). However, localities rich in large mammals are rather rare. In the south of the Russian Plain, typical subarctic and steppe small mammals occurred (*Dicrostonyx simplicior*, *Lemmus sibiricus*, *Lagurus* ex gr. *lagurus*, *Microtus gregalis*). In the Caucasus region, the tar pit Binagady fauna near Baky belongs to the same stage. Under modern conditions, the range of some animals became completely separated and confined to different biomes.

Conclusions

The data on the early and middle Pleistocene mammals from Northern Eurasia offer important insights into our knowledge of the history of mammals. These assemblages differ considerably in their composition as a result of evolutionary and migration processes. In the Pleistocene, the general trend toward global temperature decrease, changes in landscape and climatic conditions, and differentiated environmental patterns caused important changes in mammal communities within the territory at the suprageneric, generic, and species levels. The faunas demonstrate adaptation from the temperate climatic conditions of the pre-Pleistocene to the cooler and more diverse conditions at the end of the Pleistocene. A gradual disappearance is therefore noted of the Miocene–Pliocene and thermophilous forms (mastodons, giraffids, hippopotamids, hyenids) with their extinction or displacement to southern Asia or Africa, paralleled by the development of Pleistocene and modern genera and species, and the gradual emergence of associations typical for modern biomes (tundra, steppes, forest, etc.).

The main periods of turnover in mammal communities of Northern Eurasia coincided approximately with the maximum drops in global temperature, which were accompanied by large-scale transformations of the environment. The most significant changes occurred at the Pliocene–Pleistocene (2.6 Ma) and early–middle Pleistocene (0.8 Ma) boundaries. Changes in faunal composition were also reported at 1.8, 1.2, and 0.4 Ma. Beginning in the middle Pleistocene, the turnover affected mammal diversity at the generic and species levels. Immigration to and from adjacent territories played an important role in these faunal transformations.

The roots of some modern genera are found in the late Miocene (*Canis*, *Axis*, etc.), the Pliocene (*Nyctereutes*, *Ursus*, *Lynx*, *Equus*), the Gelasian (*Gulo*, *Cervus*, *Alces*, *Capreolus*, *Bison*), and the middle Pleistocene (*Camelus*, *Rangifer*, *Ovibos*, *Saiga*). The Pliocene–Pleistocene boundary is marked by the disappearance of a number of thermophilous forms. Evolutionary trends can be traced equally in the large herbivorous animals (elephants, rhinoceroses, horses, artiodactyls), various carnivores (canids, ursids, hyenids, felids), and small mammals. A clear boreal group, which comprised the ancestral forms of modern Northern Eurasian species, started to form actively at the beginning of the late early Pleistocene, around 1.8 Ma. The increasing amplitude of global cooling was then accompanied by the appearance and widespread distributions of first boreal and then arctic forms in northern Siberia and the mountainous regions of Central Asia. Boreal communities

became more widespread in the early middle Pleistocene (true wolves, tiger *Panthera tigris*) and at the end of late middle Pleistocene (Khasarian), with the first appearance of modern species (*Cervus elaphus*, *Rangifer tarandus*, *Ovibos*, *Saiga*, etc.). Zoogeographic provinciality therefore increased from the Early toward the late middle Pleistocene.

The mammalian fauna of the African continent has undergone many changes during the Neogene. Most of these occurred by the end of the Pliocene and the beginning of the Pleistocene, when the African predator guild attained its modern composition and structure, driven principally by the extinction of saber-toothed cats on the continent and the disappearance of the more archaic hyenas (Turner, 1990, 1995a; Turner and Antón, 1999). Other archaic elements of the African megafauna, such as the deinotheres, gomphotheres, and chalicotheres, also disappeared at approximately the same time. While the hominin genus *Paranthropus* went extinct, ungulates such as pigs and giraffes became less diverse and the three-toed hipparion horses became rare (Turner and Wood, 1993; Turner and Antón, 2004). In contrast, Migrants to Africa in the Pliocene and more recently thrived, adding more variety to the indigenous fauna. African faunas thus appear more modern at a much earlier date, in contrast to the situation in Eurasia and the New World, where archaic forms survived until the Holocene and the appearance of modern faunas is a very recent phenomenon. The living African mammal fauna can thus be considered largely a Pliocene relict.

Nevertheless, at the beginning of the Pleistocene the structure and composition of faunas still differed in several important ways from the pan-African fauna of today (Turner and Antón, 2004). Werdelin and Lewis (2005) suggested that this difference may have been even more marked than previously thought, at least with regard to the Carnivora. They argued that extant taxa such as the lion (*Panthera leo*), leopard (*Panthera pardus*), cheetah (*Acinonyx jubatus*), and spotted hyena (*Crocuta crocuta*) can only be traced back to the Pliocene at the genus level at best, at least in eastern Africa, instead of at the species level as previously argued by Turner (1990). They also cast doubt on previous arguments for the extinction of the machairodont cats at approximately 1.5 Ma as proposed by Turner and Antón (1999, 2004) and for the interpretations of turnover in the guild of larger Carnivora also proposed by these authors. These differences in viewpoint stem in part from differences in the tendency to split rather than lump taxa, and they will always be a part of paleontological debate. However, arguments for the splitting of the genus *Crocuta* in particular are founded in large part on unpublished data (Werdelin and Lewis, 2005, p. 128) and are therefore difficult to address. They also do not take into account the South African record.

However this difference in viewpoints is resolved, it remains true that the nature and pattern of changes within the African Pleistocene have been poorly understood, largely because well-dated deposits such as those of eastern Africa that provide our picture of Pliocene events are relatively rare or information about them is unpublished. For these reasons, relatively little synthesis of Pleistocene faunal evolution has been attempted. Fortunately, this situation is now changing, and in recent years details of several sites have appeared or the

material has been reanalyzed and deposits have been dated. As a result, overviews such as that of O'Regan et al. (2005) show that the early to middle Pleistocene faunas of Africa do not show the major changes across the boundary seen in Eurasia and the Americas at that time. Instead, they concluded that the middle Pleistocene faunas of Africa have been heavily influenced by geographic locality, such that although a small amount of turnover may have taken place, the modern zoogeographic communities in the Levantine and north African areas of the Palearctic and those of the sub-Saharan African region can be traced back as far as the early Pleistocene.

Our aim is to provide a summary of the faunas of the middle Pleistocene of Africa in order to extend previous treatments of the available data (O'Regan et al., 2005). Following a brief survey of the climatic background to the period, the discussion will be regional, focusing on northern Africa, eastern Africa, and southern Africa (Figure 1 and Table 1). West Africa has few, if any, middle Pleistocene sites; thus, it is omitted from this discussion. Many of the sites that we mention were collected from or excavated for the purposes of archaeological rather than paleontological study. Many preserve trace fossils of the genus *Homo* in the form of stone tools, which range in technology from the Acheulean to Middle Stone Age. Therefore, the presence of *Homo* is inferred from behavioral remnants as well as, in some cases, actual hominin fossils. There is thus a potential for collection bias in that the presence of archaeology is the main impetus for the continued exploration of these sites. However, it may be that, by the middle Pleistocene, hominins were such a well-established and pan-African taxon that their actual or inferred presence in these assemblages represents a real feature of their distribution in the past landscape.

The Middle Pleistocene

Climatic Background

We take the early-middle Pleistocene boundary to occur at 0.78 Ma (Berggren et al., 1995). Between 0.92 and 0.65 Ma, the climate of the Earth shifted from the smaller scale oscillations in the Pliocene and early Pleistocene to the major oscillations that characterize the middle and late Pleistocene. The change produced a large increase in global ice volume at the beginning of the interval, followed by a change in the frequency of the Quaternary Ice Ages as the 41-ka glacial cyclicity was replaced by the 100-ka glacial cyclicity by 0.65 Ma (Shackleton and Opdyke, 1976). Between 0.9 and 0.6 Ma, the interglacials were warm and arid and the glacials cool and humid in Africa (Dupont et al., 2001), but the transition to the 100 ka cyclicity brought warm and more humid interglacials and colder and drier glacials. Evidence from deep-sea cores and isolated terrestrial records (Schefuss et al., 2003) suggest that the African vegetation responded to changes in aridity, temperature, and CO₂ concentrations provoked by

Figure 1 Map showing faunal occurrences.

these climatic shifts. Recent work suggests that during the middle Pleistocene the lakes of the East African Rift System, which were focal elements of many of the sedimentary basins from which we know faunal assemblages, were at times very deep; this may correspond to a variable climate following the mid-Pleistocene revolution (Trauth et al., 2005).

North Africa

The faunal record in northern Africa is patchy, but several sites offer a chance to compare this area with other areas of Africa. In Morocco, localities near Casablanca provide the possibility to examine faunal assemblages of the region. The lower levels (L) of the Thomas Quarry sites also may date from the lower middle Pleistocene and preserve human fossils, stone tools, and some poorly preserved animal remains, including *Hippopotamus*, *Equus* (zebra) and gazelle at the lowest levels. All of the potentially middle Pleistocene sites—that is, those that postdate Ternefine (= Tighenif, thought to be early Pleistocene) have yielded remains of fossil bears, genus *Ursus*, which are completely absent in African deposits south of the Sahara. The presence of the suid *Kolpochoerus* suggested to Raynal et al. (2001) that these deposits may predate the middle Pleistocene, but without precise biostratigraphic analysis of the material it is impossible to determine whether it is a late example of the taxon, which survives until the middle or even perhaps the late Pleistocene. The absence of extinct forms from the extensive carnivore fauna contrasts with the micromammal remains, which may suggest that the site is early Pleistocene in age, since specific anatomical details of some rodents appear rather

archaic (Raynal et al., 2001). Thomas Quarry 1, which may have been redeposited secondarily, presents a carnivore-dominated assemblage with an estimated date earlier than 400 Ka.

Oulad Hamida 1 Quarry has several sites, one of which, Rhino Cave, has an abundance of the eponymous white rhino *Ceratotherium* in association with numerous Acheulean artifacts. *Camelus* is unknown in Pleistocene deposits south of the Sahara, so the Rhino Cave example may be the earliest on the continent. Numerous carnivore remains have also been recovered, although all are from extant species (Raynal et al., 2001).

The Moroccan middle Pleistocene sites yield the giant baboon *Theropithecus oswaldi* and *Equus mauritanicus*, but not *Metridiochoerus*, the antelope *Hippotragus gigas*, or the scimitar cat *Homotherium*, which Raynal et al. (2001) used to suggest that the sites postdate the lower Pleistocene as represented at Tighenif. However, it is just as likely that at least some of these apparent absences are due to environmental factors since *Metridiochoerus* is known to survive well into the middle Pleistocene. Differences in the rodent, particularly gerbil, fauna from the Rhino Cave assemblage compared with the lower levels of the Thomas Quarry site may also suggest environmental rather than temporal contrasts. For present purposes, these sites are considered as middle Pleistocene, although the potential conflation of temporal and environmental factors in identifying biostratigraphic markers is noted as problematic.

Eastern Africa

Eastern African sites are, to a certain degree, the most useful when trying to assess the nature and scope of faunal change

Table 1 Faunal occurrences

<i>Locality</i>	<i>Location</i>	<i>Age (Ma)</i>	<i>Dating method</i>	<i>Paleoenvironment</i>	<i>References</i>
Oulad Hamida 1	Morocco	~0.7–0.13	Biostratigraphy	Shoreline	Raynal et al. (2001)

Namib IV	Namibia	~0.7–0.4	Biostratigraphy		Shackley (1980)

through time. Due to a continuous history of faulting activity on the East African Rift System (EARS) and concomitant volcanic activity, the sites that preserve products of volcanism can be dated using absolute methods, such as potassium–argon or single crystal laser fusion argon–argon dating. Even when such methods are not applicable, biostratigraphic comparisons have a greater prospect of validity since they are made over smaller geographic distances.

Fossils from the Asbole area in the lower Awash Valley of Ethiopia have been dated at 0.80–0.60 Ma using biostratigraphy of the diverse mammalian fauna (Geraads et al., 2004). Extinct forms, such as the pigs *Kolpochoerus majus* and *Metridiochoerus*, are found with an early occurrence of the genus *Bos*, a new species of herpestid (mongoose), and Acheulean artifacts. In the Middle Awash Valley of Ethiopia, the Wehailu Formation has yielded a fauna assigned to the middle Pleistocene (Kalb et al., 1982a,b), whereas the Bodo Member, which has been correlated on the basis of its fauna to Olduvai Bed IV, has several extinct taxa, including the pigs *Kolpochoerus limnetes*, *K. majus*, and *Metridiochoerus*. The overlying Andalee Member may traverse the middle/late Pleistocene boundary but contains the extinct *Giraffa* cf. *G. jumae* and *Kolpochoerus majus*.

Kanjera, in Western Kenya, preserves an extensive middle Pleistocene fauna in the northern exposure members of the Kanjera Formation, which span the Brunhes–Matuyama boundary. There, *Elephas recki* is found in KN-5 in sediments deposited during the Brunhes chron, whereas other extinct taxa, such as *Metridiochoerus compactus* and *M. hopwoodi*, derive from below this, in magnetically normal sediments. The most extensive collection of fauna from the middle Pleistocene beds at Kanjera comes from the GP (Giraffe Phalanx) site, where modern taxa such as the suid genus *Phacochoerus* are found in association with species that subsequently became extinct, such as *Metridiochoerus*, *Syncerus acoelotus* (African buffalo), *Hippopotamus* cf. *H. gorgops*, and *Kolpochoerus* (Plummer, 1991; Ditchfield et al., 1999).

Lainyamok, a site west of Lake Magadi in Kenya, preserves a well-dated fauna that has some interesting characteristics (Shipman et al., 1983; Potts and Deino, 1995). This 392–330 Ka site has a fauna that is notable both for its lack of extinct forms and for the presence of modern forms occurring beyond their modern range, such as the blesbok *Damaliscus dorcus*, currently restricted to southern Africa. In many ways, Lainyamok can be considered one of the earliest well-dated modern faunas in Africa and demonstrates that, at least in some regions, an essentially modern fauna was in place here before the end of the middle Pleistocene. The site further provides a date for the disappearance of several extinct taxa that were common in older sites.

Ologesailie, in Kenya, spans the interval from the latest part of the early Pleistocene through the middle Pleistocene (Deino and Potts, 1990). The Member 10 (0.662 ± 0.004 Ma) and 11 (0.601 ± 0.003 Ma) faunas are the best described and contain a range of modern antelope genera as well as the extinct pigs *K. majus* and *Metridiochoerus* and the extinct *Hippopotamus gorgops* (Koch, 1986). The Kaphurur Formation in the Tugen Hills near Lake Baringo, Kenya, provides an extensive fauna in sediments dated from 0.75–0.23 Ma (Deino and McBrearty, 2002; McBrearty et al., 1996). Although most of the taxa recovered are extant, there are a few exceptions, such as *K. majus*. *Hippopotamus gorgops* may be represented in some of the larger hippo remains,

but *Syncerus acoelotus* is not documented. The modern chimpanzee, *Pan*, has also been reported from the Kaphurur Formation, which falls well outside of its current known geographical range (McBrearty and Jablonski, 2005).

Olduvai Gorge, Tanzania, preserves a middle Pleistocene fauna in three geological units: Olduvai Bed IV (0.83–0.62 Ma), the Masek Beds (0.62–0.40 Ma), and the lower portion of the Ndutu Beds, the oldest date for which is 0.40 Ma (Hay, 1994). Bed IV preserves *H. gorgops*, *S. acoelotus*, *M. compactus*, and *Phacochoerus antiquus*, a primitive relative of the modern warthog (Harris and White, 1979). The Masek Beds have a less diverse fauna than Bed IV and preserve all of these except *S. acoelotus*, due either to its local extinction or to sampling error. Near Lake Eyasi, Tanzania, extinct species have been recovered from the Eyasi Beds, including *Hippopotamus* aff. *H. gorgops* and large giraffids that may be *G. jumae* (Mehlman, 1987). These remains are assigned a tentative middle Pleistocene age based on calculations of sedimentation rates. Isimila, on the Iringa Plateau, may be as old as 0.26 Ma based on an early use of uranium series dating (Cole and Kleindienst, 1974). Several extinct taxa have been recovered from the site, including *M. compactus* and *K. limnetes* (Coryndon et al., 1972).

Southern Africa

The history of faunal change and movement in the southern part of Africa differs from that in the east. Although *K. limnetes*, *M. hopwoodi*, and *H. gorgops* are present in the middle Pleistocene, they all disappear by its end. *Metridiochoerus compactus*, which is locally extinct by the latest part of the middle Pleistocene in eastern Africa, is present until very late in southern Africa, with the youngest dated occurrence of 30–20 Ka from Redcliffe Cave, Zimbabwe (McKee et al., 1995). The extant *Syncerus caffer* is known throughout the middle Pleistocene, but *S. acoelotus*, which is more commonly found in East Africa, is not documented from southern sites on the continent.

Two localities in Zambia, Mumba Falls and Twin Rivers, preserve fossils that date to the later part of the middle Pleistocene (Barham, 2000). Fauna from Twin Rivers is scanty and fragmentary but is associated with Lupemban stone tools. There is no evidence that any extinct species were present (Bishop and Reynolds, 2000). The middle Pleistocene assemblage from Mumbwa Cave is also very small; however, the presence of an antilopine bovid is unusual. Gazelles and springboks have not been known from the Zambezian Zone during historic times (Klein and Cruz-Urbe, 2000).

The majority of South African sites are caves and thus have different geological derivation and depositional history from those in eastern Africa, which are almost exclusively open-air sites. They may be sampling different local environments, which may or may not be representative of wider regions. When comparing sites from more than one region, it is important to note differences that are ecological rather than temporal in nature, although distinguishing between the two can be difficult. McKee et al. (1995) observed that species such as *Hippopotamus amphibius*, which has a long temporal range but a very narrow ecological one, has a very patchy distribution in the cave sites of southern Africa and is not useful for dating sites.

McKee et al. (1995) consider Cornelia to be a middle Pleistocene site notable for the absence of archaic *Homo sapiens*,

which is otherwise present at most of the southern African localities of this age. Elsewhere in southern Africa, archaic *H. sapiens* is usually found with a higher proportion of extant species than have been recovered at Cornelia (McKee et al., 1995). Indeed, more than 60% of the taxa recovered from the site are extinct, which presents a stark contrast to the situation in eastern Africa toward the end of the middle Pleistocene. *Hipparion libycum*, an archaic three-toed horse, has its last appearance in the southern African faunal record there, suggesting that it may be one of the oldest middle Pleistocene sites in the region.

Elandsfontein (= Hopefield = Saldhana) in the Western Cape Province preserves an extensive fauna and has been suggested to date from the first half of the middle Pleistocene (0.7–0.4 Ma) (Klein and Cruz-Urbe, 1991). The majority of the remains recovered are from extant taxa, but a few archaic forms, such as the antelope *Antidorcas recki*, *Metridiochoerus andrewsi*, *Theropithecus oswaldi*, and *Megantereon*, have what may be their last appearances. However, it has long been recognized that the deposits at the site have no clear date; the assemblage probably represents a considerable palimpsest derived from hyena dens and almost certainly includes earliest Pleistocene taxa (Hendey, 1974; Turner, 1990; Turner and Antón, 1999). It is notable that the archaic taxa span a number of biological families and ecological preferences, suggesting that these disappearances are temporal rather than ecological phenomena. The fact that so little of the assemblage was influenced by human agents reinforces this conclusion, allowing hominin activity to be ruled out as a potential taxonomic bias in the composition of the faunal assemblage.

Duinefontein 2, Western Cape Province, is an excavated site that preserves an extensive fauna in association with Acheulean artifacts (Klein et al., 1999). The fossil bone is extensively damaged by carnivores, with little evidence of hominin processing of bone. The ecological preferences of the fauna suggest that the local environment was grass-and-bush mosaic with standing water nearby. Klein et al. (1999) suggested that the fauna is similar in morphology and/or size to examples from nearby Elandsfontein Main. With the exception of *Equus capensis*, there are no definite examples of extinct species, leading to a biostratigraphic estimate of ~0.4 to ~0.2 Ma.

Gladysvale, a cave in Gauteng Province, has yielded assemblages that date from the Pliocene to the middle Pleistocene. The middle Pleistocene external deposits have produced a carnivore fauna that, although scanty, is modern. A few archaic ungulates, including a late occurrence of the South African ovibovine *Makapania* as well as *Pelorovis* and *Equus capensis*, have been recovered, but the remaining ungulates are extant forms.

The fauna from the Cave of Hearths in the Makapansgat Valley, Limpopo Province, suggests that the site was formed later than Elandsfontein and Cornelia. The presence of Acheulean artifacts, which are relatively developed from a technological standpoint, along with remains of *H. sapiens rhodesiensis*, reinforces this conclusion (McKee et al., 1995.) Some extinct forms of antelope, such as *Megalotragus* and *Pelorovis*, were recovered there, but the pig *Phacochoerus* is modern.

Florisbad, in the Free State of South Africa, preserves several extinct taxa in combination with Middle Stone Age artifacts and remains of archaic *H. sapiens*. It may be the most recent site

in South Africa that can be characterized as middle Pleistocene in age. As is the case at the Cave of the Hearths, the extinct large antelopes *Megalotragus* and *Pelorovis* were present at Florisbad, so the relative dating is based as much on the technology and hominin biostratigraphy as on other factors (Kuman and Clarke, 1986).

In southwestern Africa, the site of Namib IV within the central Namib Desert preserves *Elephas recki* along with other faunal and archaeological elements indicative of a middle Pleistocene age (ca. 700–400 Ka) (Shackley, 1980). Although this site adds little to our understanding of the composition of middle Pleistocene faunas, it extends considerably the geographic range over which we can document their presence.

Overview of the African Middle Pleistocene Mammal Fauna

We might expect, based on the evidence from other areas of the world (Azzaroli et al., 1988; Turner, 1995b), that the changes in climate summarized previously and any attendant vegetational responses would have impinged upon African mammals very directly. However, the change to the 100-ka cyclicity does not appear to have greatly affected the faunas because, although there are some changes, the turnover is largely attritional rather than a marked event (O'Regan et al., 2005). Approximately 0.70 Ma, several new species appeared, including the modern *H. amphibius*, the reedbuck, and the black wildebeest. Klein (1984) noted that at the other extreme of this time interval, several large mammalian species became extinct without issue, at or before the middle/late Pleistocene boundary. These include *Theropithecus oswaldi* and the elephantids *Loxodonta atlantica*, *E. recki*, and *E. iolensis*. Several suid species, including *Kolpochoerus limnetes* and *Metridiochoerus modestus*, also disappear by the end of the middle Pleistocene, as do the giraffids *Giraffa jumae*, *G. gracilis*, and *Sivatherium maurusium*. The majority of antelope extinctions occur somewhat earlier, but a species of *Tragelaphus*, along with *Thalcerocerus radiformis*, three species of the genus *Parmularius*, and the alcelaphine *Beatragus*, have their last occurrences in the middle Pleistocene, which also sees the end of the genus *Hipparion* (Klein, 1984). Although the precise timing of their disappearances is difficult to determine, due to both a paucity of samples and the problems of absolute dating during this time interval, there are no known occurrences at late Pleistocene sites.

Conclusions

With some exceptions, African mammalian faunas have remained quite stable throughout the Pleistocene. During the middle Pleistocene, there are a few extinctions, the exact timing of which is not precisely determinable, and a few new species also arise. Changes in the geographical ranges of some modern taxa can also be seen so that occurrences of the blesbok *Damaliscus dorcas* in Lainyamok and the chimpanzee *Pan* in the Kapthurin Formation of Kenya fall outside of their historical ranges. This review of fossil assemblages from the middle Pleistocene supports the suggestion that the development of the African large mammal fauna is characterized by fluctuations in species associations

and geographical ranges that may have been responses to short-term or rapid fluctuations in climate (Potts and Deino, 1995, p. 111).

Mid-Pleistocene of Australia

G J Prideaux, Western Australian Museum, Perth, WA, Australia

This article is reproduced from the previous edition, volume 2, pp. 1517–1537 © 2007, Elsevier B.V.

Introduction

Australia (including New Guinea) separated from Antarctica in the early Paleogene, with a unique mix of Gondwanan and more cosmopolitan lineages aboard. For most of the Cenozoic, as the continent drifted northward from higher to lower mid-latitudes, intercontinental migration to and from Australia was severely constrained by significant transoceanic dispersal distances. This long isolation resulted in a terrestrial vertebrate radiation shaped largely by shifts in dominant vegetation types driven, in particular, by a general drying trend beginning in the middle Miocene. Much of Australia's Pleistocene vertebrate radiation can be envisaged as the evolutionary end-product of 15 million years of adaptation to increasingly drier conditions (Prideaux, 2004). This chapter reviews the zoogeography of the middle Pleistocene vertebrates of Australia, then briefly compares the fauna with what is known of the preceding and succeeding faunas.

Paleobiology and systematics of Pleistocene vertebrates have previously been reviewed by Murray (1991) and others. Accounts of early discoveries and development of the field of Pleistocene vertebrate paleontology in Australia are provided by Rich and Van Tets (1985) and Ride and Davis (1997). Reconstructions of a range of extinct Pleistocene vertebrates have been presented in Quirk and Archer (1983), Rich and Van Tets (1985) and Murray (1991). The approach taken in this chapter builds upon the work of Hope (1982) and Horton (1984), two pioneering studies in the analysis of Australian Pleistocene vertebrate distributions in relation to climate.

Caveats

Our understanding of the stratigraphy and chronology of Pleistocene vertebrates in Australia is poor compared with that of the continents in the Northern Hemisphere. This results from several factors, including the lack of widespread episodic ice sheets, isolation from intercontinental faunal interchange, a relative paucity of localities yielding sufficient taxonomic diversity, limitations of conventional dating techniques, too few detailed stratigraphic studies, and insufficient basic exploration. Significant improvements have been made over the past decade, facilitated by advances in dating methods and by more rigorous selection and study of sites. A middle Pleistocene (780 000–126 000 years ago) age was not confirmed for any Australian site by absolute dating until the publication of Ayliffe et al. (1998). No middle Pleistocene sites have yet been identified in New Guinea. Perusal of the pre-1998 literature reveals that the default age of 'late Pleistocene' has often been applied to assemblages lacking apparent phylogenetic precursors to later forms or containing any marsupials believed not to have persisted into the Holocene (Prideaux, 2004). In a

sense, 'late Pleistocene' (herein, 126 000–10 000 years ago) and 'Pleistocene' have often been treated as synonyms. So, while Australia presents a unique opportunity to study the responses of a fundamentally different vertebrate fauna to Quaternary environmental change, the necessary temporal framework is only just beginning to take shape.

Taxon occurrences within dated middle Pleistocene deposits are considered here, along with those of undated assemblages of possible or likely middle Pleistocene age. The Australian record is not yet adequately understood to facilitate the differentiation of Middle and earlier late Pleistocene faunas, so it is certain that at least some undated 'middle Pleistocene' assemblages included herein will eventually be found to be of last glacial age. Middle Pleistocene occurrences for all vertebrate species (Tables 1–3) are plotted within provinces based largely on Australia's modern climatic zones (Figures 1–2). Mammal species recorded in more than one province are plotted on the distribution maps (Figures 3–7).

Zoogeography

Frogs

Frogs are the only amphibians represented in the Australian Cenozoic record. Three families (Hylidae, Myobatrachidae, Microhylidae), 10 genera, and 24 species have been recognized from the middle Pleistocene (Table 1), but this assessment is the result of just two locality surveys. Tyler (1977) identified the ilia of five frog species in the Main Fossil Chamber deposit of Victoria Fossil Cave in the Naracoorte Caves World Heritage Area of southeastern South Australia (Figure 8). All those species are still present in the region today. Absence of the now locally common *Litoria raniformis* from Tyler's sample is the only current evidence suggesting change in the Naracoorte frog fauna since the middle Pleistocene. However, much more frog material has been retrieved from Victoria Fossil Cave and other variously-aged cave deposits in the region over the past three decades and should be a source of paleoclimatic information when eventually studied. An appraisal of the middle Pleistocene frog fossils from the Mt. Etna cave-fills near Rockhampton in coastal northeastern Queensland (Figure 9) reveals a fauna indicative of conditions wetter than exist in the area today (Hocknull, 2005). Deposits recognized as early Pliocene by biocorrelation have now been dated and are evidently middle Pleistocene in age (SA Hocknull, pers. comm., June 2005). The giant *Etnabatrachus maximus* is the only frog known from the middle Pleistocene of Australia that is now extinct.

Reptiles

Crocodyles

Strata in northern South Australia documented by Tedford and Wells (1990) have yielded the only dated middle Pleistocene

Table 1 Middle Pleistocene frog and reptile records of Australia by province. Bold letters indicate dated middle Pleistocene records; plain letters indicate possible (undated) middle Pleistocene records. Taxonomic uncertainty is indicated by '?'. Only taxa identified to genus or below are included. Unequivocally extinct species indicated by '†'

occurrences of crocodiles in Australia (Figure 10). Material has been referred to the large extinct *Pallimnarchus pollens* and, tentatively, to the extant estuarine crocodile *Crocodylus porosus*. Both taxa also occur in fluvial deposits of southeastern Queensland of possible middle Pleistocene age (Table 1). Remains of the poorly understood ziphodont crocodilian *Quinkana* have been collected from a cave deposit in the same region, while *Q. fortirostrum* is recorded from the Chillagoe Caves of northeastern Queensland (Molnar, 1981). The presence of middle Pleistocene crocodiles in the North Province accords with their current distribution throughout the estuaries and rivers of tropical Australia. Their occurrences in what are now subtropical and arid regions may reflect a more southerly extending summer monsoonal system, a phenomenon which occurred periodically during the Pleistocene (Magee et al. 2004). The effect of this may have been a more consistent flowing of the Diamantina (Warburton) River and Cooper Creek systems, which today carry monsoonal rains from central Queensland into the Lake Eyre Basin of inland Australia.

Turtles

Only four turtles of known or possible middle Pleistocene age have been identified to genus level or below (Table 1), the widespread extant chelids *Chelodina longicollis* and *Emydura macquarii*, which are known from cave deposits in southeastern

South Australia (Reed and Bourne, 2000), and two extinct, giant horned turtles, *Ninjemys oweni* and *Meiolania* cf. *platyceps*. *N. oweni* is recorded with certainty only from King's Creek on the Darling Downs in southeastern Queensland, but a specimen from northeastern New South Wales may also be referable to this species (Gaffney, 1996). No site on King's Creek is known to be of middle Pleistocene age, although it would be extraordinary if *N. oweni* did not occur in the region before the late Pleistocene. The same must also be said of the Lord Howe Island horned turtle, *M. platyceps*, and its Walpole Island neighbor, *M. mackayi*, which both come from undated horizons. The Wyandotte Local Fauna of far northeastern Queensland has yielded *M.* cf. *platyceps* (Gaffney, 1996). The Pleistocene distribution of Australian mainland meiolaniids falls entirely within the North and Upper East Provinces, which today are characterized by high summer rainfall and tropical and subtropical climates, respectively (Figures 1–2).

Snakes

The remains of snakes (especially vertebrae) are common in Pleistocene cave deposits, but have not been studied in detail. Apart from the identification by Smith (1976) of three locally extant elapid species in the middle Pleistocene of the Naracoorte Caves (Table 1), no other members of extant groups have been identified to genus level or below. The main focus

Figure 1 Climatic zones of Australia forming the basis for provinces recognized in this chapter. (Reproduced from Bureau of Meteorology, 1989. Climate of Australia, Australian Government Publishing Service, Canberra, with permission.)

of research has been the systematics of the madtsoiid *Wonambi naracoortensis*. This species is known from south-western and southeastern Australia, and a possible middle Pleistocene deposit in the Wellington Caves of central eastern New South Wales (Scanlon, 2005). The closely related

genus *Yurlunggur* is represented in the Wyandotte Local Fauna of northeastern Queensland by material unidentifiable to species (Scanlon, 2005). Like the meiolaniids, the Australian Pleistocene madtsoiids represent end-members of a Gondwanan radiation.

Figure 2 Median annual rainfall distribution of Australia. (Reproduced from Bureau of Meteorology, 1989. *Climate of Australia*, Australian Government Publishing Service, Canberra, with permission.)

Lizards

Australian Pleistocene lizard faunas have been the subject of little study. [Smith \(1976\)](#) remains the only primary study of a middle Pleistocene assemblage from southern Australia (Victoria Fossil Cave, Naracoorte). With the exception of the giant varanid *Megalania prisca*, the Naracoorte middle Pleistocene lizards thus far identified ([Table 1](#)) are all locally extant, which suggests that environmental conditions were at least broadly similar to present. [Hocknull \(2005\)](#) provided a census of the lizard fossils from the Mt Etna cave-fills ([Figure 9](#)) in the North Province, interpreting the presence of a species of the agamid *Hypsilurus* and the relative abundance of the skink *Cyclodomorphus gerrardii* to indicate a wetter environment than today, which agrees with the frog and mammal data. *M. prisca* is the only lizard with a middle Pleistocene record known to have subsequently become extinct. Although an uncommon faunal element wherever found, it was widely distributed through the eastern half of the continent from

the northeast tropics to the temperate southeast ([Reed and Hutchinson, 2005](#)). Modern mean annual rainfall throughout this range varies from ~150 to ~800 mm ([Figure 2](#)).

Birds

[Baird \(1991\)](#) provides a comprehensive review of the Australian Quaternary bird record. At least 36 families of known or possible middle Pleistocene age have been collected from many localities across Australia, but many represent singular finds and are indeterminate even to genus level. The only substantial middle Pleistocene bird fauna (41 species) known comes from the caves of southeastern South Australia ([Table 2](#)). Most of these species have modern records in the region, but four became extinct subsequent to the accumulation of the cave deposits in which they are represented: the giant flightless *Genyornis newtoni* (a dromornithid), the giant mallee fowl, *Progunya naracoortensis*, the giant coucal, *Centropus*

Figure 3 Middle Pleistocene records of mammal species with a mainly southern distribution.

colossus, and the logrunner, *Orthonyx hypsilophus*. Judging from the habitat preferences of their closest living relatives, the latter three species may have been adapted to woodland or forest. Three of four extant species (*Gallinula mortierii*, *Calyptorhynchus lathami*, *Pezoporus wallicus*) that no longer occur in the region, because of human-induced range contractions in the late Holocene, prefer similar habitats. The fourth regionally extinct species is the inland dotterel, *Peltohyas australis*, which is restricted today to arid inland Australia. *Genyornis* was widespread inland during the Pleistocene, and it is possible that, along with several of the mammals with middle Pleistocene records in southeastern South Australia (Southeast Province), *Genyornis* and *Peltohyas* extended southeastward during drier intervals. The presence of now-extinct endemic flamingos and flamingo-like palaelodids (Table 2) suggest more permanent and substantial water bodies in northern South Australia during the middle Pleistocene than exist in the region today.

Mammals

Monotremes (Ornithorhynchidae, Tachyglossidae)

Four monotremes occur in known or likely middle Pleistocene sites in Australia (Table 3), including the extant platypus, *Ornithorhynchus anatinus*, and short-beaked echidna, *Tachyglossus aculeatus*. The presence of *Ornithorhynchus* in fluvial deposits

of the Darling Downs and southeastern New South Wales (Figure 4) is congruent with its modern distribution through the waterways of subtropical and temperate eastern Australia (Strahan, 1995). *Tachyglossus* is currently distributed across the entire continent, so its presence in the Southwest, Southeast and Upper East Provinces during the middle Pleistocene is unsurprising. Remains of two giant extinct echidnas, '*Zaglossus*' *hacketti* and *Megalibgwilia ramsayi*, have been retrieved from caves in southwestern Australia. The latter also occurs in the Naracoorte Caves in the Southeast Province, and in Pleisto Scene Cave (Murray and Goede, 1977), the only dated middle Pleistocene locality in Tasmania (Roberts RG, pers. comm., September 2005; Figure 3). Echidnas are consistently rare in whichever Pleistocene assemblages they are found, so their absence from northern and inland sites should not be taken as evidence of absence from these regions.

Thylacines (Thylacinidae)

The last captive thylacine (*Thylacinus cynocephalus*) died in Tasmania in 1936 and the species is now presumed extinct, having disappeared from the mainland about 3 000 years ago. Middle Pleistocene deposits across the south and east of mainland Australia have yielded remains of *T. cynocephalus* (Table 3, Figure 6). It has not yet been recorded from inland Australia, nor possible middle Pleistocene sites in the north.

Figure 4 Middle Pleistocene records of mammal species with a mainly eastern distribution.

T. cynocephalus is absent from the Pleisto Scene Cave sample studied by Murray and Goede (1977), although its extensive Quaternary record in Tasmania suggests that it would also have occurred there during the middle Pleistocene.

Dasyurids (Dasyuridae)

Only two middle Pleistocene dasyurid assemblages have been documented, one from the Naracoorte Caves (Reed and Bourne, 2000) and a second from the Mt. Etna cave-fills (Hocknull, 2005). Most other dasyurid records (Table 3) constitute 'incidental' finds made during the collection of mega-faunal remains, and most of these represent the larger taxa (i.e., species of *Sarcophilus* and *Dasyurus*). As with other small vertebrates, there is a significant taphonomic bias against the preservation of small dasyurid remains in fluvial deposits. Among the Naracoorte middle Pleistocene dasyurids no longer inhabiting the local area, the two *Dasyurus* species became locally extinct in the late 1800s, while *Ningaui yvonnae* occurs in early Holocene strata (McDowell, 2001). *Sarcophilus* apparently disappeared from southern mainland Australia during the late Holocene, before European settlement. *Antechinus agilis*, *A. swainsonii* and *Phascogale calura* have no post-middle Pleistocene records at Naracoorte. However, with the exception of *Sarcophilus* (Tasmanian devil), all of these taxa have modern records elsewhere within the Southeast Province (Strahan,

1995). The *Antechinus* and *Dasyurus* species occur within more mesic areas of Victoria (mainly higher rainfall coastal habitats), while *N. yvonnae* and *P. calura* have modern records in semi-arid mallee habitats further to the north (Strahan, 1995). More refined biostratigraphic and paleoecological studies of the Pleistocene assemblages of the Naracoorte Caves are required before such distributional shifts can be interpreted as evidence of climate-driven faunal change in the region.

Bandicoots (Peramelidae, Thylacomyidae)

Most bandicoot species thus far retrieved from deposits of known or possible middle Pleistocene age (Table 3) have latest Pleistocene or Holocene records in the same regions. However, the Mt Etna cave-fills (Figure 9) represent a major exception. These sites include a remarkable 10 different bandicoots, consisting of the eight species listed in Table 3 and two unnamed extinct taxa (Hocknull, 2005). No more than four species are known to locally co-occur anywhere in the late Pleistocene, and only in a tiny area of northeastern Queensland rainforest do three species co-occur today (Strahan, 1995). While this may reflect considerable time-averaging and some marked climate-driven local habitat changes, it is worth noting that each of the four modern bandicoots recognized at Mt. Etna (*Chaeropus ecaudatus*, *Isodon obesulus*, *Perameles bougainville*, *Macrotis lagotis*) have recent records within a wide range of

Figure 5 Middle Pleistocene records of mammal species that occur in the inland province and eastern Australia. Two of these species are also known from the South Central province.

habitats and areas differing markedly in total annual rainfall and season-ality of rainfall (Strahan, 1995; Figure 2).

Koalas (*Phascolarctidae*)

Two koala species have been recognized in the middle Pleistocene of Australia (Table 3, Figures 4–5), the modern *Phascolarctos cinereus*, and the 30% larger, but morphologically very similar, *P. stirtoni*. The taxonomic validity of the latter species deserves reinvestigation; it may simply represent a larger morph of *P. cinereus*. This species has a wide modern distribution through the sclerophyll forests and woodlands of mainland eastern Australia. Although present in the Middle and late Pleistocene of the southwest, the species did not persist there into the Holocene.

Wombats (*Vombatidae*)

Wombats were widespread across the continent during the middle Pleistocene (Table 3). Morphological evidence suggests that, like the modern *Vombatus ursinus*, *Lasiorninus krefftii*, and *L. latifrons*, all six extinct Pleistocene wombats were grazers, including the widely distributed, ~200 kg *P. gigas* (Figure 7). The middle Pleistocene records of *V. ursinus* largely conform with its modern distribution through the moderate to higher rainfall areas of southeastern and eastern Australia, including

Tasmania (Figure 4). A close relative, *V. hacketti*, is well-represented in middle Pleistocene cave deposits in the southwest but, as with the koala, it had become extinct by the latest Pleistocene. The small, gracile *Warenda wakefieldi* is known only as a rare element in the cave deposits of southeastern South Australia and southwestern Victoria. Middle Pleistocene wombat diversity appears to have been greatest in the Lower East and Upper East Provinces (Figures 3–4, 7).

Diprotodontoids (*Diprotodontidae*, *Palorchestidae*)

middle Pleistocene remains of at least five diprotodontoids and two palorchestids are known (Table 3). Their large body sizes (ranging in body weight from ~500 to ~2 000 kg) mean that their fossils are among the most conspicuous species in many localities, even though they are rarely abundant in any one assemblage. *Zygomaturus trilobus* was widespread through temperate southern and eastern Australia, extending no further north than southeastern Queensland (Figure 6). *Nototherium inerme* overlaps with the similarly-sized *Z. trilobus* in the Upper East Province, but is otherwise known only from the North Province (Figure 7), including a locality near Kununurra in the northwest (pers. obs.). Several *Diprotodon* species have been named, although their taxonomic validity remains unclear. Nevertheless, most authorities have agreed that at least two

Figure 6 Middle Pleistocene records of mammal species that are widely distributed through southern and eastern Australia.

species existed, including *D. optatum*, the largest marsupial ever to have lived. *D. optatum* was one of the most widespread Pleistocene marsupials, ranging from the tropical north, through arid inland Australia, to the temperate south (Figure 7). There are no middle Pleistocene records of *D. optatum* in the southwest or Tasmania, but it is known from the late Pleistocene of King Island in Bass Strait, off the north coast of Tasmania. Two palorchestid species occur in deposits of known or possible middle Pleistocene age, but they remain unknown outside of mesic eastern Australia (Figure 4).

Marsupial lions (*Thylacoleonidae*)

Thylacoleo carnifex is the most commonly preserved large mammalian carnivore in the middle Pleistocene of Australia (Table 3, Figure 7). There are some subtle variations in body size and morphology across southern Australia, but whether these are taxonomically significant is unclear. Although the specimen of a large *Thylacoleo* species from the Mt. Etna cave-fills (Figure 9) in the North Province preserves insufficient features to definitively identify it to species (Hocknull 2005), it may be tentatively referred to *T. carnifex* since no other similar-sized thylacoleonids are known from the Pleistocene. *T. hilli* is a diminutive species recovered from Mt Etna as well as Curramulka Town Well Cave on Yorke Peninsula in South

Australia (Figure 4), a locality which has also yielded *T. carnifex* (Pledge 1977).

Possums (*Burramyidae*, *Pseudocheiridae*, *Petauridae*, *Acrobatidae*, *Phalangeridae*)

By far the most diverse middle Pleistocene possum assemblage thus far sampled is from the Mt. Etna cave-fills in the North Province (Table 3). Hocknull (2005) has recognized 17 species, including representatives of all five extant families, although none has yet been identified to species level. Such high species richness suggests a highly diverse floristic environment (including rainforest habitats), marked temporal changes in prevailing habitats, or a combination of both. Records for the six southeastern species are derived from the middle Pleistocene deposits of the Naracoorte Caves (Reed and Bourne 2000; Table 3), and each of them still occurs today within woodland or heathland habitats in southeastern South Australia. Similarly, *Pseudocheirus peregrinus* and *Trichosurus vulpecula* persist in the woodlands and forests of the Southwest Province, and the latter has modern records in the South Central Province (Strahan, 1995).

Kangaroos (*Hypsiprymnodontidae*, *Macropodidae*)

Kangaroos are the most conspicuous and diverse group of Late Cenozoic marsupials. In species richness and abundance, they

Figure 7 Middle Pleistocene records of mammal species that have either very wide (most species) or predominantly northern distributions (*Nototherium inerme*, *Macropus pearsoni*).

dominate the > 1-kg-body-weight component of most middle Pleistocene faunas. At least 72 species occur in known or possible middle Pleistocene sites (Table 3). The extinct, possibly omnivorous, propleopine hypsiprymnodontids are represented in eastern Australian deposits by three rare and poorly understood *Propleopus* species, but the group is unknown in Tasmania and west of longitude 137° E. Their inland middle Pleistocene record is restricted to one molar fragment referred to *Propleopus oscillans* from the Kutjitarra Formation of northern South Australia (pers. obs.; Figure 5).

At least nine potoroine macropodids are known from the middle Pleistocene (Table 3). *Borungaboodie hatcheri* is an extinct giant bettong represented by a single specimen from ~140ka sediments in Tight Entrance Cave in the Southwest Province (Prideaux, 1999). *Bettongia pusilla* persisted in the Nullarbor region into the Holocene (McNamara, 1997), but was not recorded there in modern times. Six potoroines are known from middle Pleistocene deposits of the Naracoorte Caves in the Southeast Province (Reed and Bourne, 2000); none occurs in the area today, although most have local late Holocene records. Today, *Aepyprymnus rufescens*, *Bettongia gaimardi*, and *Potorous tridactylus* inhabit wooded areas with median annual rainfalls ranging from 600 to 1600 mm, while most modern records of *Bettongia penicillata*, *B. lesueur*,

and *P. platyops* are in areas with an annual rainfall of 600 mm or less (Strahan, 1995; Figure 2). Even slight temporal fluctuations around the present-day 600-mm annual rainfall for the Naracoorte Caves may have been sufficient to facilitate the local occurrence of these six potoroines. The remaining regional middle Pleistocene records for potoroines are consistent with modern records of the species (Figures 3–4).

The extinct sthenurine macropodids (short-faced kangaroos) were browsers of sclerophyllous or xeromorphic vegetation, and were widespread and diverse during the middle Pleistocene. Sthenurine distributions group into several general patterns, that is species principally distributed through:

- southern and eastern Australia;
- south central and inland Australia;
- southern, eastern and inland Australia; and
- eastern and inland Australia (Prideaux 2004; Figures 3–7).

There are no published Pleistocene records of sthenurines north of latitude 26° S in central and eastern Australia, and they are unknown north of 31° S in Western Australia. Given the rarity and low diversity of larger marsupials so far retrieved from the North Province, the absence of evidence for sthenurines should not yet be taken as evidence of absence from tropical and subtropical arid Australia.

Figure 8 The Main Fossil Chamber in Victoria Fossil Cave, Naracoorte Caves World Heritage Area, southeastern South Australia (Southeast Province), preserves the richest and most diverse assemblage of middle Pleistocene vertebrates in Australia. (Photo courtesy of S Bourne.)

Figure 9 Cave-fills exposed on the side of Mt. Etna, near Rockhampton in northeastern Queensland, preserve the only diverse succession of middle Pleistocene vertebrates from northern Australia (North Province). (Photo courtesy of S Hocknull.)

Macropodines ('modern' kangaroos and wallabies) account for more than half of the macropodid species recorded from the middle Pleistocene (Table 3). Subsequent to the accumulation of the deposits in which they are represented, 26 macropodine species have become extinct, three of these since European settlement (*Lagorchestes leporides*, *Macropus greyi*, *Onychogalea lunata*). Four middle Pleistocene genera have no modern representatives: the tree-kangaroo genus *Bohra*, the wallaby genus *Congruus*, and two genera of large browsing kangaroos, *Protemnodon* and *Troposodon*. Species of *Bohra* are known from the Mt. Etna cave-fills (Hocknull, 2005), Wellington Caves in the Lower East Province, and caves on the Nullarbor Plain in the South Central Province (pers. obs.). This suggests that *Bohra* was less restricted to well-wooded habitats

Figure 10 Middle Pleistocene channel-fills intercepted by the Cooper Creek, northern South Australia (Inland Province), yield a diverse array of vertebrate remains. (Photo courtesy of R Wells.)

Figure 11 Three recently discovered caves on the Nullarbor Plain in Western Australia (South Central Province) have produced a remarkable array of well-preserved skeletons of middle Pleistocene vertebrates, including several new kangaroo taxa. (Photo courtesy of L Hatcher.)

than extant tree-kangaroos of the genus *Dendrolagus*, which are limited in distribution to the tropical rainforest of far northeastern Queensland and New Guinea (Dawson, 2004). Although poorly known until recently, species of *Congruus* were distributed across southern Australia and extended into the lower east (Dawson, pers. comm. July 2005; pers. obs.; Figure 3). The large browsing *Protemnodon* species are represented in most Australian middle Pleistocene assemblages (Figures 5, 7). Two *Troposodon* species have been retrieved from known or possible middle Pleistocene deposits (Figures 4–5). *T. minor* occurs in the Kutjitarra Formation of northern South Australia (Tedford and Wells, 1990), and in the Wellington Caves and Darling Downs deposits along with *T. kenti*. Both species are also known from the late Pliocene, apparently browsed tough vegetation, and were convergent upon the sthenurines in some craniodental attributes (Prideaux, 2004). *Macropus* is the most diverse fossil and modern macropodine genus, and at least 17 species have middle Pleistocene records (Table 3), including representatives of the three subgenera, *Macropus*, *Notamacropus*, and *Osphranter*. Only six *Macropus* species are known from the western half of Australia; four have records in the southwest caves and five occur in the Nullarbor caves (Figure 11).

Rodents (Muridae)

Murid rodent fossils have been recorded from known or possible middle Pleistocene localities in all major regions except for the Upper East Province (Table 3). Only *Conilurus* has been tentatively recorded from the inland (Tedford and Wells, 1990). The predominance of fluvial localities in the Upper East and Inland Provinces has resulted in a major taphonomic bias against the preservation of rodent remains. The two most diverse middle Pleistocene rodent assemblages are from the Mt. Etna cave-fills (Hocknull, 2005) in the north and the Naracoorte Caves in the southeast (Reed and Bourne, 2000). None of the Mt. Etna species has yet been identified to species, but each of the 13 Naracoorte species either remain locally extant or persisted there until the late Holocene (McDowell, 2001), probably until the arrival of Europeans.

Bats (Vespertilionidae, Megadermatidae)

As with dasyurids and murid rodents, remains of bats are usually only encountered after the application of wet-screening techniques. At present, there are only two dated and three possible middle Pleistocene bat records (Table 3). Each of the three nominal species is extant, and no record lies outside of current ranges.

Comparison with the Early Pleistocene Record

Only a handful of Australian sites have been recognized as early Pleistocene in age, based largely on the reversed magnetic polarity of the fossiliferous sediments (Whitelaw, 1991; Tedford, 1994). By far the most faunally diverse site is situated near Portland in southwestern Victoria (Flannery and Hann, 1984). Several undescribed species apparently express stages of evolution intermediate between late Pliocene and middle Pleistocene relatives, although the first detailed study of its fauna is only now being undertaken (Piper K, pers. comm., October 2005). All genera presently recognized at Portland persisted into the middle Pleistocene elsewhere, with the exception of an as-yet-undescribed ektopodontid possum (Rich, 1991).

Comparison with the Late Pleistocene Record

Absence or very low diversity of megafaunal species in Australian localities younger than ~50 ka is the only biostratigraphic marker presently useful for differentiating late Pleistocene assemblages from those of middle Pleistocene age, although sound evidence for persistence into the late Pleistocene has been retrieved for only 19 of the roughly 50 megafaunal species. However, given the paucity of dated Australian sites within the 126–50 ka period, and the previous rarity of many of these species in the middle Pleistocene, 19 of 50 species probably represents a substantial underestimate of the number that became extinct during the late Pleistocene (Prideaux, 2004). Whether extinction of the megafauna, and a range of often-overlooked medium-sized taxa, was prolonged or occurred relatively rapidly at the end of this interval, remains to be effectively established.

Ongoing Research

Although several general distribution patterns are evident within the 'time-averaged' middle Pleistocene vertebrate fauna of Australia (Figures 3–7), the current data are extremely limited geographically and temporally. A detailed understanding of the regionally variable influences of climatic fluctuations on vegetation structures and taxon distributions will emerge only after many more years of focused research. Ongoing studies into the middle Pleistocene vertebrate record of Australia are centered on five main topics:

- (1) Discovery and analysis of assemblages from regions for which the existing records are least understood (e.g., Tasmania, North Province);
- (2) Biostratigraphic studies documenting and interpreting shifts in species diversity and relative abundance within well-stratified sequences (e.g., Naracoorte Caves);
- (3) Paleocological analyses combining traditional morphological and relative abundance methods with stable isotopic and enamel microwear techniques;
- (4) Taphonomic studies describing and comparing site accumulation mechanisms and resultant biases in the fossil record.
- (5) Application of multiple geochronologic methods (e.g., U-series, optically stimulated luminescence (OSL)) to the dating of key sites.

Introduction

The middle Pleistocene in Europe is characterized by multiple faunal exchanges that were mainly controlled by climatic oscillations. The definition of the early middle Pleistocene boundary is still a matter of debate among Quaternary geologists, stratigraphers, and paleontologists. Some authors strongly support the placing of the beginning of the middle Pleistocene at the Matuyama/Bruhnes paleomagnetic reversal (ca. 0.78 Ma) (XII INQUA Congress), whereas other researchers correlate the base of the middle Pleistocene with Marine Oxygen Isotopic Stage (MIS) 25, dated around 0.9 Ma (see Gliozzi et al. (1997)). A wider consensus among Quaternary geoscientists places the middle late Pleistocene boundary at 0.125 Ma, correlated with MIS 5e.

The middle Pleistocene vertebrate record must be considered against a backdrop of the latest early Pleistocene bio-events, since these form the basis for the definition of middle Pleistocene terrestrial vertebrate communities. Vertebrate paleontologists are used to subdividing geological time using biochronological or biostratigraphical scales. These are based on the evolutionary degree of the faunal elements of the assemblages and on dispersal events. Two different biochronological scales are in use for the middle Pleistocene in Europe. The first is based on micromammals and spans from the Biharian to the early middle Toringian; in particular the fossil assemblages are biochronologically divided on the basis of water voles belonging to the *Mimomys savini*–*Arvicola mosbachensis* lineage (Koenigswald and Kolfschoten, 1996; Maul et al., 1998) (Figure 1).

The other biochronological scale is based on large mammals and spans from the Galerian to the middle Aurelian (*sensu* Gliozzi et al. (1997)). The term Galerian was introduced by Ambrosetti et al. (1972) to define a particular faunal assemblage in Europe. An updated and more accurate biochronological definition is given by Gliozzi et al. (1997), who considered Galerian to be a ‘Mammal Age’ marked by the first appearance in Italy of the large-sized megacerine deer *Praemegaceros* (= *Megaceroides* = *Megaloceros*) *verticornis* (Figure 2).

In the literature, the vertebrate faunas referable to the early middle Pleistocene and having a similar composition to the Galerian fauna were often referred to as Cromerian or Tiraspolian but, as stated by Azzaroli et al. (1988) the first term ‘defines a stage based on pollen and of much shorter duration than Galerian,’ whereas the second one, based on a faunal complex from Moldova and used for Russian and Eastern Europe deposits, has to be restricted to the younger part of the Galerian. At present, the data collected and analysed from Dutch and UK deposits support the evidence for as many as four and possibly five ‘Cromerian Complex’ interglacials, although these may not all be of full interglacial status.

On the basis of the Italian fossil record, post-Galerian faunas that are still referable to the middle Pleistocene have been attributed to a different, younger Mammal Age, the Aurelian (Gliozzi et al., 1997). The Aurelian is marked by the first appearance in Italy of the giant deer *M. giganteus*, the ‘modern’ wolf *Canis lupus* and the cave bear *Ursus spelaeus*.

These ‘Mammal Ages’ have subsequently been further subdivided into faunal units on the basis of bio-events that produced changes in the composition of assemblages.

During the last three decades many paleontologists established biochronological frameworks mainly based on the fossil record of their own countries, for example: (1) faunal units (FUs), Italy (Gliozzi et al., 1997); (2) mammal zones (MNQs), Western Europe (Guerin, 1990); and (3) mammal assemblage zones (MAZs), Great Britain (Schreve, 2001). A general comparison of such schemes reveals that, despite the overall regional significance of many of the biochronological units, and the uncertain chronological position of some fossiliferous localities, bio-events of wider significance can be defined and correlated at a European scale (Figure 1).

In this article, the faunal changes and the evolutionary trends witnessed during the late early Pleistocene and middle Pleistocene in the terrestrial ecosystems of Europe are placed into three different ‘episodes’ of general biochronological significance: (1) the latest early Pleistocene (Villafranchian–Galerian transition); (2) the early middle Pleistocene; and (3) the late middle Pleistocene.

The Latest Early Pleistocene (Villafranchian–Galerian Transition)

The faunal renewal recorded in terrestrial vertebrate faunal assemblages of Europe during the latest early Pleistocene is known as the ‘end Villafranchian’ dispersal event (Azzaroli et al. (1988), and references therein). Furthermore, the same authors underlined that the transition between Villafranchian and Galerian did not take place at once. Subsequent further discoveries and new studies continued to provide more data on this transitional phase. Moreover, new terms have since been proposed to define such an informal biochron, referable to faunal assemblages calibrated with the base of the Jaramillo submagnetochron (Protogalerian, Caloi and Palombo (1996) and Epivillafranchian, Kahlke (2001)).

During the latest early Pleistocene, a series of dispersals started in Eurasia, involving mammals of Asiatic and African origin and probably related to climatic change.

Large felids such as *Puma* and the dirk-toothed cat *Megantreon*, together with large-sized deer such as *Eucladoceros*, are recorded for the last time and then become extinct. Among the ungulates *Bison* and *Praemegaceros* occur and their presence

continues to characterize subsequent middle Pleistocene faunal assemblages.

In SW Europe, faunal assemblages referable to the early Galerian, are present at Colle Curti (Central Italy) and Redicicoli (Roma) in Italy ([Glozzi et al., 1997](#); [Milli and Palombo, 2005](#)), Le Vallonet (Alpes Maritimes) in France ([Lumley et al., 1988](#)), Huéscar 1 and Cullar de Baza 1 (Granada), and Sierra de Atapuerca (Burgos) in Spain ([Alberdi et al., 1997](#), and references therein; and Bermudez de Castro et al., 2004, and references therein).

At Colle Curti, together with *P. verticornis*, several Villafranchian taxa, such as the cervid *Axis eurygonos*, the hunting dog *Lycan lycaonoides*, the giant hyaena *Pachycrocuta brevirostris*, the saber-toothed cat *Homotherium latidens*, the mammoth *Mammuthus meridionalis*, a small rhino (*Stephanorhinus* sp.), and the rodents *Pliomys lenki* and *Microtus* (*Allophaiomys* sp.) occurred. In the Vallonet cave deposits, the rich 'fossil assemblage 3' has been referred to the Jaramillo magnetochron and includes 25 taxa, with several carnivores and, amongst the ungulates, *Ammotragus europaeus*. Rodents are represented by *Microtus* (*Allophaiomys*) *nutiensis*, *Ungaromys nanus*, and *Mimomys* cf. *savini* ([Lumley et al., 1988](#)).

In Spain, a large number of mammal species are represented at different sites located in the Sierra de Atapuerca (Burgos) (e.g., Trinchera Dolina, Trinchera Elefante). The mammal assemblages recorded by the entire stratigraphic

sequence at Trinchera Dolina span from the late early to the middle Pleistocene. In particular, Trinchera Dolina level 6 (TD6) has yielded one of the most ancient fossil hominin assemblages recorded thus far from Western Europe, dated to approximately 0.8 Ma (Bermudez de Castro et al., 2004). At Trinchera Elefante the occurrence and the relative abundance of *Hippopotamus* and *Castor* among mammals, and of *Anas* and the sea eagle *Haliaeetus* among birds, provides evidence of the presence of inland water biotopes.

In Northern and Central Europe, the fossiliferous locality of Untermassfeld (Thuringia, Germany) can be considered as one of the most representative of the late early Pleistocene.

Since its discovery, in 1978, on the right slope of the river Werra, this site has been intensively excavated. Until present, more than 9500 determinable large mammals and 3000 microvertebrates have been discovered and 64 vertebrate taxa have been defined (toads and frogs amongst the amphibians; reptiles including skinks, geckos, and pond tortoises; and birds including swans, geese, birds of prey, gallinaceous, and crows) (Kahlke (2001), and references therein).

In the large mammal assemblage, ungulates are represented by an unusual species of bison (the long-legged *Bison menneri*) and the cervids (*Eucladoceros giulii* and *Capreolus cusanoides*). Despite the presence of several Villafranchian elements (e.g., *Megantereon*, *Puma*, *Pachycrocuta*, and *Eucladoceros*), Markova and Kolfschoten (2005) highlight a discrepancy with the biochronological framework proposed by Kahlke (2001), because of the occurrence at Untermassfeld of voles very similar to those recorded at Podumci 1 (Croatia), close to Matuyama–Brunhes boundary (Markova and Kolfschoten (2005), and references therein). For this reason these authors suggest a younger age for the faunal assemblage of Untermassfeld.

The Early Middle Pleistocene

The first occurrence in Europe of the steppe mammoth *Mammuthus trogontherii* and of the red deer *Cervus elaphus acoronatus* can be considered as bio-events characterizing the oldest early middle Pleistocene faunas (middle and late Galerian). The typical Galerian fauna spread over Europe giving rise to new adaptations, in particular among the ungulates. Moreover, at the end of this period, the climatic deterioration referable to the Elsterian (Anglian) glacial stage provided the ecological basis for the appearance of the cold-stage faunal grouping generally known as the ‘*Mammuthus–Coelodonta* faunal complex,’ which characterized the late middle and late Pleistocene of the Northern Hemisphere (Kahlke, 1999).

Among bovids, different large-bodied taxa became a very important element of the middle Galerian faunas such as *Bison schoetensacki*, and the ovibovine *Praeovibos* and *Ovibos*. In late Galerian faunas the aurochs *Bos primigenius* appeared and, together with the water buffalo *Bubalus murrensis*, spread into Northern Europe during temperate climatic stages.

An interesting bubaline bovid is ‘*Bos*’ *galerianus*, known only by a fragmentary skull from Cava di Breccia di Casal Selce (Ponte Galeria area, Rome, Italy; Figures 3(a) and (b) (Petronio and Sardella, 1998), which has been recently referred to the genus *Hemibos* (Martinez Navarro and Palombo,

2004). Even if the taxonomic position of this species is still a matter of debate, its biogeographical significance is important, probably indicating a dispersal from the Levant.

Cervids are quite common and provide detailed data that are very useful for biochronological purposes. The middle and late Galerian are represented by *P. verticornis*, replaced by *Praemegaceros solilhacus* (Figure 4) at approximately 0.6 Ma.

Figure 3 Fossil bones recorded in the Ponte Galeria area (Roma, Italy): (A) ‘*Bos*’ *galerianus* skull frontal view; (B) ‘*Bos*’ *galerianus* skull occipital view; (C) *Praemegaceros verticornis* antler. Drawings by R. Sardella.

Figure 4 Reconstruction of *Praemegaceros solilhacus*. Drawing by G. Di Stefano, modified from Di Stefano, G. Petronio, C. and Sardella, R. 2005 – Large bovid and cervids from latest Villafranchian–Galerian faunas of Italy. QUATERNAIRE (*International Journal of the French Quaternary Association*) Hors-serie-n. 2: 95–102.

The endemic British megacerine *Praemegaceros* (= *Megaloceros*) *dawkinsi* is closely related to *P. solilhacus*. Another megacerine lineage is represented by *Megaloceros savini*.

The red deer *Cervus elaphus* became quite common during the Galerian and is represented by different subspecies that are considered to be of great biochronological significance: *Cervus elaphus acoronatus* and *Cervus elaphus priscus* (found in the middle Galerian), and *Cervus elaphus eostephanoceros* (found in the late Galerian) (Figure 5) (Di Stefano and Petronio, 1993). In addition, around 0.6 Ma, the large-bodied fallow deer *Dama clactoniana* appears, while the Villafranchian cervid *Axis* (= *Pseudodama*) *eurygonos* survives until the end of early middle Pleistocene (Di Stefano and Petronio (2000–2002), and references therein).

Rhinos are represented by three species: *Stephanorhinus hundsheimensis*, *Stephanorhinus hemitoechus*, and *Stephanorhinus kirchbergensis*; amongst the equids *Equus altidens* and the large-sized *Equus suessenbornensis* occur. They represent different lineages, better adapted to highly seasonal and even very cold climates (Azzaroli et al., 1988). *M. trogontherii* and the straight-tusked elephant *Elephas* (*Palaeoloxodon*) *antiquus* characterize different faunal assemblages of the early middle Pleistocene, surviving until the end of the middle Pleistocene and the end of the late Pleistocene respectively.

Among carnivores the giant short-faced hyaena *P. brevirostris* become extinct at the beginning of middle Pleistocene and

was ecologically replaced by the spotted hyaena *Crocota crocuta praesplaea*, an African immigrant. Lion and leopard are widespread and the large felid *Panthera gombaszoegensis* become extinct during this period. The cave bear lineage is represented by *Ursus deningeri*, but the Himalayan black bear *Ursus thibetanus* and the brown bear *Ursus arctos* are recorded in several localities (Palombo and Valli, 2004). Canids are represented by the middle-sized wolf *Canis mosbachensis*, the hunting dog *L. lycaonoides*, and the dhole *Cuon priscus*.

The evolutionary changes in voles of the genus *Microtus* are stratigraphically important in Western and Southern Europe; furthermore in Central and in Eastern Europe as well as in Asia, the evolution of the lagurids has also yielded additional information about the biochronology of faunal assemblages (Markova and Kolfshoten, 2005).

Middle Galerian mammal faunas are quite well represented in Europe. In Italy, the Slivia local fauna (Trieste) is considered to be representative of the earliest middle Galerian (Slivia Faunal Unit – FU, *sensu* Gliozzi et al. (1997)). From the Slivia karst infill the first occurrences of species that were to spread out widely in the Italian peninsula during the middle Pleistocene are recorded (i.e., *B. schoetensacki* and *S. hemitoechus*) together with the last occurrence of *P. brevirostris* and the water vole *Mimomys savini*.

The most complete middle Pleistocene stratigraphical succession crops out in the Ponte Galeria area (Rome), where at least three different faunal assemblages have been discovered. The earliest faunal assemblage comes from Fontignano, where the ‘cold’ rodents *Prolagus pannonicus* and *Predicrostonyx* sp. have been found (Petronio and Sardella (1999), and references therein; Milli and Palombo (2005)). Petronio and Sardella (1999) defined the Ponte Galeria FU for the faunal assemblage recorded in the area giving its name to the Galerian Mammal Age. This faunal assemblage is dated at ca. 0.75 Ma and includes *M. trogontherii*, *M. savini*, *P. verticornis* (Figure 3(c)), *A. eurygonos*, ‘*B. galerianus*’ (Figures 3(a) and (b)), and *Crocota crocuta praesplaea*.

The second faunal assemblage from this area is referable to the Isernia FU. Together with bison, deer, equids, and small mammals (the hamster *Allocricetus bursae* and the water vole *A. mosbachensis*), birds, reptiles, and amphibians have been found. The avifauna includes the partridge *Perdix palaeoperdix* and the vulture *Gyps melitensis*, together with the ‘Villafranchian survivor’ *Palaeocryptonyx* (Bedetti, 2003). Moreover, the fossil record from this site includes avian species prevalently inhabiting lacustrine and marshy areas (i.e., Anatidae), not commonly recorded in the Galerian localities in the rest of Europe, which are dominated by terrestrial birds, such as Galliforms and Corvids (Bedetti, 2003).

The Clactonian fallow deer first occurs in the more recent Isernia FU (ca. 0.6 Ma, Coltorti et al. (2005)), together with *P. solilhacus*. The age of this well-known archaeological site, particularly rich in remains of *B. schoetensacki* and *S. hundsheimensis*, was for many years, matter of debate among researchers. The K/Ar age of 0.736 Ma, provided by Coltorti et al. (1982), was considered too old in comparison to the paleontological evidences (e.g., occurrence of *A. mosbachensis* and *P. solilhacus*) (Kolfshoten and Koenigswald, 1996; Petronio and Sardella, 1999). The new radiometric data provided by Coltorti et al. (2005) confirm the value of the biochronological framework established for Italy. Coeval

Figure 5 Reconstruction of *Cervus elaphus eostephanoceros*. Drawing by G. Di Stefano, modified from Di Stefano, G. Petronio, C. and Sardella, R. 2005 – Large bovid and cervids from latest Villafranchian-Galerian faunas of Italy. QUATERNAIRE (International Journal of the French Quaternary Association) Hors-serie-n. 2: 95–102.

fossiliferous localities from Italy are Venosa, Valdemino, and Visogliano (Glozzi et al., 1997).

In Spain, the middle Galerian is attested by the faunal assemblage of Sierra de Atapuerca, in particular Trinchera Dolina (TD4). In France fossiliferous localities of comparable age are rather poorly represented. These faunal assemblages are referred to biochrons MNQ21 and MNQ22 and are characterized by the first occurrence of *Panthera pardus*, *U. thibetanus*, *Cervus elaphus acoronatus*, and *U. deningeri*. The association of *P. brevirostris* and *Cervus elaphus acoronatus* is particular to this stage (Palombo and Valli, 2004). According to Abbazzi and Lacombat (2005, and references therein) the local fauna of Soleilhac (Haute Loire), previously calibrated with a submagnetochron of Jaramillo and therefore related to the latest early Pleistocene, must be considered younger than supposed before and referable to the Isernia FU because of the co-occurrence of *Cervus elaphus acoronatus*, *D. clactoniana*, and *P. solilhacus*. Other approximately coeval French localities are Lunel Viel and L'Escale (Palombo and Valli, 2004). In France MNQ22 is characterized by the first occurrence of the modern brown bear *U. arctos*, the thar *Hemitragus bonali*, and the rhino *S. hemitoechus*. Finally, MNQ23 is diagnosed by the occurrence of the badger *Meles thoralis spelaeus*, the wolf *C. mosbachensis* (= *C. lunellensis*), and the cave lion *Panthera leo spelaea*.

In Greece the following Galerian faunal assemblages can be listed: Maratousa, Volos, and Petralona (Kahlke (2001), and references therein).

The large mammal fossil record in Central Europe (Germany, The Netherlands, Belgium, Czech Republic, and Austria) presents a general biochronological framework similar or, in some aspects transitional, between Eastern and Western Europe. The detailed studies on the rich micromammalian record provide a biochronological scheme for Central Europe based mainly on rodents and, in particular on the *Mimomys-Arvicola* lineage (Maul et al., 1998; Koenigswald and Heinrich, 1999). One of the most important European early middle Pleistocene mammal fauna is that from the Main Fossiliferous Horizon ('Hauptfundschrift') of Voigstedt (Thuringia, Germany), referred to as the '*Mimomys savini* faunas,' where 18 micromammals have been found. The site is also the type locality of the ground squirrel *Spermophilus dietrichi* and of the flying squirrel *Petaurium voigstedtensis* (Maul (2002), and references therein). Large mammals include typical middle Galerian species such as *M. trogontherii*, *P. verticornis*, and *B. schoetensacki*. In Thuringia other important fossiliferous localities are Süssenborn, Rastenberg, and Bad Frankenhausen, yielding faunal assemblages from a cold stage earlier than the Elsterian glaciation, as testified by the occurrence of cold climate-adapted elements such as the ovibovine *Soergelia elisabethae* (Süssenborn and Rastenberg), the reindeer *Rangifer tarandus*, and the ovibovines *Praeovibos priscus* and *Ovibos moschatus* (Bad Frankenhausen). The Bad Frankenhausen faunal assemblage represents the first Central Europe occurrence of the *Coelodonta-Mammuthus* complex (Kahlke (1999), and references therein).

Other important Galerian fossil assemblages coming from Central and Eastern Europe include: Karlich C, D, and E, Mauer, Mosbach 2 (Germany), Kozi Grzbiet (Poland), Hundsheim (Austria), Stranska Skala (Moravia, Czech Republic), Koneprusy C718 and Přezletice (Bohemia, Czech

Republic), Gombasek 1 (Slovakia), Kövesvár and Vértesszőlős 1 and 2 (Hungary), Betfia VII and Feldioara Cariera (Romania), and Tiraspol (Moldova) (Kahlke (2001), and references therein).

The younger 'early *Arvicola mosbachensis* (= *A. cantiana*) faunas' (sensu Koenigswald and Heinrich (1999)) are characterized by the first occurrence in Central Europe of *E. (Palaeoloxodon) antiquus* and *A. mosbachensis*, and the widespread dispersal of *Homo* at higher latitudes. This 'faunal zone' includes cold and warm stages. *E. (Palaeoloxodon) antiquus* seems to leave Central Europe during colder phases, while this species, together with *Hippopotamus amphibius*, becomes quite common during warm stages, even in the Rhine valley. This biochronological unit can be represented by the faunas from Mauer and Mosbach 2 in Germany (Koenigswald and Heinrich, 1999).

Steppe adapted taxa, together with northern Palearctic tundra elements, such as reindeer, spread as far as the Pyrenees and characterize the late Galerian faunas recorded at La Caune de l'Arago (Tautavel, France). In this locality *Rangifer* has been found together with *Vulpes* cf. *praeglacialis*, *Equus mosbachensis*, *Bison priscus*, *P. priscus*, *Ovis ammon*, and many other taxa (Kahlke, 1999; Palombo and Valli, 2004). This biochron can be compared to the Italian Fontana Ranuccio FU, although the cold climate-adapted taxa are missing from the latter.

The Brunhes-Matuyama paleomagnetic boundary has not yet been established in Britain, although the mammalian faunal record from the middle Pleistocene onward is very detailed. In Britain six early middle Pleistocene assemblages of temperate-climate affinity have been recognised (Stuart et al., 2004), all of which predate the Anglian glaciation (MIS 12), a major stratigraphical marker for NW Europe. However, more detailed correlations with the marine oxygen-isotope record are not yet well established.

Over almost two centuries the exposures of the Cromer Forest Bed Formation on the Norfolk and Suffolk coasts have provided the most important fossil record for the early middle Pleistocene of Britain. One of the richest localities is West Runton with a large number of different taxa recorded (45 mammals, 17 birds, 3 reptiles, 5 amphibians, and 7 fishes) (Stuart, 1996).

The presence at Pakefield (Suffolk) of the vole *Mimomys pusillus*, a species that disappears from the continental record after MIS 16, may indicate that this site alone predates MIS 16 whereas all others, including the typesite of the Cromerian Complex at West Runton (Norfolk) belong to the latest part of the early middle Pleistocene (MIS 15 and 13 inclusive). The presence at Pakefield of *H. amphibius*, *P. dawkinsi*, *E. (Palaeoloxodon) antiquus*, and *E. altidens* provides evidence for 'Mediterranean' climates that are substantially warmer than southern Britain at the present day, as well as evidence for the oldest human occupation in the country (Stuart et al., 2004; Parfitt et al., 2005).

Other important localities are Sidestrand, Sugworth (Berkshire), and Little Oakley (Essex) characterized by the occurrence of *M. savini*. In contrast, Ostend (Norfolk), Boxgrove (West Sussex), and Westbury-sub-Mendip (Somerset) which contain *A. mosbachensis* and are thus referred to a younger 'Cromerian Complex' interglacial that postdates the Cromerian stratotype at West Runton (Stuart, 1996).

The Late Middle Pleistocene

In the late middle Pleistocene almost all the Villafranchian elements of the mammal faunas became extinct and the distribution of the European terrestrial vertebrates was strongly affected by climatic oscillations. The ‘*Elephas antiquus*–*Stephanorhinus kirchbergensis* faunal complex’ spread into Northern latitudes across Europe during temperate stages; from the Saalian cold stages onward the diffusion of the ‘*Mammuthus*–*Coelodonta* faunal complex’ took place in the Mediterranean region, with more advanced faunal elements (e. g., large-sized true wolf) if compared to the early middle Pleistocene faunas. Such a complex characterizes the glacial late Pleistocene times (Kahlke (1999), and references therein).

A useful tool for establishing long distance correlations and creating an accurate biochronological framework for the late middle Pleistocene vertebrate faunas comes from the detailed analysis of fluvial terrace sequences yielding different faunal assemblages, for example, the river Thames in Britain or the Tiber in Italy.

The Aurelian faunas include a large number of modern taxa, or closely related species, differing from extant associations in the occurrence of large mammals (horses, rhinos, hippos, elephants, wolves, hyaenas, lions, and leopards). The name Aurelian derives from the Via Aurelia, which crosses the area NE of Rome, where a great number of fossiliferous localities have been discovered. In Italy the beginning of the Aurelian Mammal Age is indicated by the first occurrence of the giant deer *Megaloceros giganteus*, *U. spelaeus*, and *C. lupus* and is correlated with MIS 9, ca. 0.3 Ma (Gliozzi et al., 1997). Early Aurelian faunas (MIS 9–8) are included in the Torre in Pietra FU (early Aurelian). In the time span represented by these faunal assemblages *E. (Palaeoloxodon) antiquus* and *B. primigenius* are particularly abundant and widespread in Italy (Milli and Palombo, 2005). Faunal assemblages dated to the interval between MIS 7 and 6 are included by Gliozzi et al. (1997) in the Vitinia FU (middle Aurelian). The appearance of the fallow deer *Dama dama tiberina*, *Equus hydruntinus*, and *Mammuthus* specimens showing advanced skull features have been regarded as peculiar to the Vitinia FU. However, Milli and Palombo (2005) remark that differences in composition of the faunal complexes ascribed to Torre in Pietra and Vitinia FUs are minimal, both from the taxonomical and the structural point of view, thus both of them could be referred to MIS 9.

In France the early Aurelian can be related to the biochron MNQ24, characterized by the first occurrence of *Saiga tatarica*, *U. spelaeus*, *Capra ibex*, and *Coelodonta antiquitatis*.

Rich vertebrate fossil assemblages are recorded in cave deposits with archaeological layers in Southern France (Lazaret and Terra Amata), in sequences referred to MIS 7–6 (Palombo and Valli, 2004).

The sequence for the late middle Pleistocene in Britain is now very comprehensively described and consistent faunal differences have been identified between the various temperate episodes of this period (Schreve, 2001).

The British evidence has one particular advantage if compared to the evidence from NW Europe (France, The Netherlands, and Germany), since, although the last interglacial is already defined at oxygen-isotope substage level, the

mammalian evidence has identified much smaller-scale environmental and climatic oscillations within MIS 11 and 7 (and more tentatively within MIS 9), possibly corresponding to isotopic substages. Three post-Anglian interglacials are represented in the record from the lower Thames valley, as typified by the sites of Swanscombe (MIS 11), Purfleet (MIS 9), and Aveley (MIS 7) in descending relative age, each of which has yielded a diagnostic mammalian assemblage (Schreve, 2001).

The deposits at Swanscombe preserve a fluvial sequence which can be considered as the oldest terrace of the Lower Thames and is related to MIS 11. The interglacial represented at Swanscombe also witnesses the first appearance in Britain of four taxa that are not found in the preceding Cromerian Complex: *S. kirchbergensis*, *S. hemitoechus*, *M. giganteus*, and *B. primigenius*. Furthermore, the large fallow deer *D. clactoniana*, the equid *E. hydruntinus*, and the cave bear *U. spelaeus* occur. Among micromammals the small mole *Talpa minor*, the giant beaver *Trogontherium cuvieri*, the rabbit *Oryctolagus cuniculus*, and the European pine vole, *Microtus (Terricola) subterraneus* have been recorded.

The Purfleet MAZ is based mainly on the terrace correlated to MIS 9 exposed at Purfleet, near London. The rich faunal assemblage includes mammals, birds, amphibians, and fishes. Among mammals, *E. antiquus*, *Macaca sylvanus*, and water voles referable to the transitional *A. mosbachensis/A. terrestris* occur; among fishes the presence of cyprinids and of their associate predator, the pike, clearly indicate temperate climatic conditions.

The mammalian assemblages correlated to MIS 7 have been subdivided into two biochrons, the Ponds Farm MAZ and Sandy Lane MAZ. Both assemblages are present at Aveley (Essex). The Sandy Lane MAZ has a distinct composition, with the coexistence of a particular late morphotype of *M. trogontherii* with *E. antiquus*, *Equus ferus*, and *S. kirchbergensis*.

The comparison of the terrace sequence of Thames with the Wipper River terrace system (Thuringia, Germany) reveals clear affinities. Bilzingsleben II, a rich paleontological and archaeological deposit, has been correlated to MIS 11 and to the fauna compared with the Swanscombe MAZ (Schreve and Bridgland, 2002).

In Central Europe the ‘younger *Arvicola mosbachensis* (= *A. cantiana*) faunas’ (sensu Koenigswald and Heinrich (1999)) reflect a period of strong climatic oscillations and a decrease of biodiversity, followed by a temperate climatic phase, when *B. primigenius* and *B. murrensis* dispersed into Central Europe. Finally, the ‘*Arvicola mosbachensis/terrestris* faunas’ also include *Apodemus maastrichtensis* representing the final part of middle Pleistocene, before the Eemian.

Introduction

Pleistocene vertebrate faunas from North America are abundant, taxonomically diverse, and widespread across much of the continent. These faunas thus provide a reasonably detailed and robust record of faunal change during an interval that witnessed numerous advances and retreats of glacial ice. The terms ‘early Pleistocene’ and ‘middle Pleistocene’ are not formally defined in North America, nor is their sporadic use necessarily consistent with informally designated and recognized units on other continents. The term ‘late Pleistocene’ in North America also is not formally defined, but is commonly used for faunas that fall within the temporal resolution of radiocarbon dating techniques.

Several extensive stratigraphic sequences deposited over the last few million years, combined with numerous faunas associated with reliable external age control, make the Pliocene and Pleistocene vertebrate faunal record of North America among the best in the world. These sequences are situated in the midwestern and western portions of the continent, including the Anza-Borrego Desert and San Timoteo Badlands of southern California, the Ringold Formation in southeastern Washington State, the San Pedro and Gila River valleys in Arizona and New Mexico, The Snake River Plain in Idaho, and the Meade Basin in Kansas.

External age control for these faunas (i.e., age determinations independent of the faunas themselves) are derived from both paleomagnetic analyses of the sediments associated with the faunas, and from radio-isotopic dating techniques. In the absence of these external controls, faunas are often placed in an approximate chronological sequence on the basis of biochronological inference (relying on taxonomic similarity with externally-dated localities in nearby regions). By the mid-1960s, four magnetic polarity chrons were established for the time interval considered here. From oldest to youngest they are the Gilbert, Gauss, Matuyama, and Brunhes. These names, and the subchron designations encompassed by them, are still widely used in the literature for North American faunas. Alternative, numerical designations for magnetic chrons from the Mesozoic through Miocene were recently extended through to the present (Opdyke and Channell, 1996), and these numeric designations are being used more frequently in modern literature.

The mammals are by far the best-studied group of vertebrates from the early and middle Pleistocene of North America. They constitute a taxonomically diverse assemblage, are abundant in many faunas within this time range, are found in fossilized deposits across most of the continent, and are widely used as tools to help establish age relationships among faunas in this interval. Therefore, it is appropriate to begin this summary discussion with a review of the significant mammalian record.

North American Land Mammal Ages

Most vertebrate paleontologists in North America utilize a formal nomenclature centered on North American land mammal ages originally proposed by Wood et al. (1941) and Savage (1951). There are three land mammal ages relevant for this discussion; these are (from oldest to youngest) the Blancan, Irvingtonian, and Rancholabrean. These are faunal terms that are based on, and differentiated by, the taxonomic composition and stage of evolution of the mammalian fauna in North America. They are often (erroneously) used as operational synonyms with the traditional Lyellian epochs, or are otherwise confused with formal and informal time-stratigraphic units. The history, development, structure, operational framework, and current understanding of these mammal ages were addressed in detail by various authors in two useful compendium volumes (Woodburne, 1987, 2004). Traditionally, these mammal ages were conceptualized as being applicable across the entire North American continent, but a recent formal proposal restricting their latitudinal scope to regions south of 55°N was based on an emerging consensus that northern latitude faunas in Canada and Alaska are sufficiently distinct during the Pliocene and Pleistocene to merit independent biochronologies (Bell et al., 2004b). The same is likely also true of faunas in the southern latitudes of central America; presumably a boundary line would be drawn somewhere in Mexico, but there are insufficient data available at this time to warrant any formal proposal for restricting Mexican faunas from the traditional North American mammal ages.

The relatively recent formal recognition of boundaries between the classic late Cenozoic epochs, and the accompanying designation of stratotypes for those boundaries, has led to a refined assessment of the correspondence between mammal age boundaries and epochal boundaries. The base of the Pliocene Series is now interpreted to be 5.335 Ma. The base of the Pleistocene series is now approximately 1.77 Ma. The Holocene is not formally defined, but in North America it is operationally recognized as beginning at the conveniently round number of 10,000 years ago. As currently defined and understood (see below), the Blancan mammal age begins between 5.2 to 4.6 Ma and extends to the base of the Irvingtonian, at approximately 1.35 Ma. Therefore, most of the Blancan is within the Pliocene Epoch but the youngest Blancan faunas (those between 1.77 Ma and 1.35 Ma) are earliest Pleistocene in age. An informal designation of those latter faunas as ‘latest Blancan’ was recently proposed by Bell et al. (2004b). As currently defined and understood (see below), the Irvingtonian begins at approximately 1.35 Ma, and extends to the poorly-constrained beginning of the Rancholabrean, some time between 210 ka and 160 ka. The Irvingtonian is entirely within the Pleistocene. The Rancholabrean is considered to

end with extinction of the large-bodied megafauna in North America, south of latitude 55°N. This extinction event (see [Late Pleistocene Megafaunal Extinctions](#)) was time-transgressive, but its termination is currently interpreted to be at approximately 9,500 years ago. Most of the Rancholabrean is, therefore, Pleistocene in age, extending only a few hundred years into the Holocene. The Rancholabrean is discussed elsewhere in this volume (see [Late Pleistocene of North America](#)).

Blancan

The Blancan is defined by the earliest appearance in North America, south of latitude 55°N, of the arvicoline rodents *Mimomys*, *Ogmodontomys*, and *Ophiomys*. These are extinct vole-like rodents with readily recognizable teeth, being fairly common in Blancan faunas throughout much of North America. *Ogmodontomys* and *Ophiomys* are among many taxa that are found only in Blancan faunas; others include the ground sloths *Megalonyx leptostomus* and *Glossotherium chapadmalense*, the rabbits *Aluralagus*, *Sylvilagus webbi*, *Pewelagus dawsonae*, and *Pratilepus kansasensis*, the beavers *Dipoides rexroadensis* and *Procastoroides*, the volelike rodents *Guildayomys*, *Hibbardomys*, *Nebraskomys*, and *Pliophenacomys*, the lemmings *Mictomys vetus* and *Pliolemmus*, the muskrats *Pliopotamys* and *Ondatra idahoensis*, the cotton rats *Sigmodon curtisi* and *S. minor*, the dogs *Borophagus diversidens* and *Canis lepophagus*, the bear *Ursus abstrusus*, the peccaries *Platygonus bicalcaratus* and *P. pearcei*, and the horse *Nannipus peninsulatus*. All of these taxa are extinct, but living representatives of *Sylvilagus*, *Mictomys*, *Sigmodon*, *Canis*, and *Ursus* are still found in North America. Taxa that first appear in the earlier parts of the Blancan but persist into the Irvingtonian or even younger faunas include the giant xenarthran *Glyptotherium*, shrews of the genus *Blarina*, the rabbit genus *Sylvilagus*, the American cheetah *Miracinonyx inexpectatus*, the saber-tooth cat *Smilodon gracilis*, and the elephant *Stegomastodon*. With the exceptions of *Blarina* and *Sylvilagus*, these taxa now are extinct.

The recently proposed definition of the Irvingtonian ([Bell et al., 2004b](#)) resulted in a somewhat awkward situation in which faunas that were for many decades considered to be earliest Irvingtonian are now considered to be latest Blancan. That new definition is not universally accepted, and other definitions are possible ([Bell et al., 2004b](#)) and are used operationally for some important faunas ([Martin et al., 2003](#)). In recognition of this, a distinction is made for taxa that first appear in these latest Blancan faunas and persist into younger faunas (see [Early Pleistocene](#)). These include the ground sloths *Nothrotherium* and *Paramylodon harlani*, the giant armadillo *Holmesina*, the jackrabbit *Lepus*, the voles *Allophaiomys*, *Microtus*, and *Phenacomys*, the lemmings *Synaptomys*, *Mictomys kansasensis* and *M. meltoni*, the muskrats *Neofiber* and *Ondatra annectens*, the tree squirrel *Sciurus*, the scimitar cat *Homotherium*, the peccary *Platygonus vetus*, and the mastodon *Mammut americanum*. Most of the listed rodent and rabbit genera still have living representatives in the North American fauna.

The relatively long time frame of this mammal age is reflected by the diversity of mammals represented in Blancan

faunas, and the readily apparent changes in the composition of these faunas throughout the mammal age. These changes permit the recognition of shorter intervals of time within the Blancan, and thus a more refined mammalian biochronology. Several authors over the last four decades proposed various formal designations to establish such refinement. The simplest of these proposals entailed a twofold division of the Blancan, with the older faunas united under the term Rexroadian, and the younger ones under the name Senecan ([Schultz et al., 1978](#)). That two-fold system was based on faunas from the Great Plains and the faunal sequence preserved in outcrops along the Snake River Plain. The terms are most commonly applied to faunas in those areas, and there has been minimal effort to expand the conceptual framework to other areas on the continent.

Two other efforts to divide the Blancan were based on changes in the arvicoline rodent fauna through the Blancan. Following their earliest appearance in the fossil record nearly five million years ago, arvicoline rodents rapidly diversified and expanded their geographical range across most of the Holarctic. They also appear to be characterized by a rapid rate of evolutionary change. They are widely utilized for stratigraphic correlation throughout the Holarctic. Arvicoline divisions of the Blancan were discussed extensively by [Martin \(1979\)](#), [Repenning \(1987\)](#), [Repenning et al. \(1990\)](#), and [Bell \(2000a, b\)](#). In current form there are three recognized arvicoline divisions of the Blancan. The first of these spans approximately 4.9 to 4.1 Ma and is defined by the first appearance of *Ogmodontomys* and *Ophiomys*. The second spans approximately 4.1–2.5 Ma and is defined by the first appearance of muskrats in North American faunas. The third interval begins at approximately 2.5 Ma and is defined by the earliest appearance of bog lemmings in North America; it ends with the beginning of the first Irvingtonian arvicoline division (discussed below).

Blancan faunas are found throughout much of the continental United States, but the most important localities are concentrated in the western states, Florida, and the Great Plains regions of Nebraska, Kansas, and northern Texas. Temporally equivalent faunas are also known from northern Alaska, and Michoacan, Guanajuato, Aguascalientes, and Baja California Sur in Mexico. These faunas were reviewed recently by [Bell et al. \(2004b\)](#).

Irvingtonian

There is currently no consensus on an appropriate definition for the Irvingtonian. A committee of Quaternary mammalian paleontologists in North America recently completed a paper in which they proposed to formally and explicitly define the Irvingtonian based on the earliest appearance of mammoths of the genus *Mammuthus* in North America south of latitude 55°N latitude ([Bell et al., 2004b](#)) (see [Early Pleistocene](#)). This definition is concordant with an informal proposal suggested by [Kurten and Anderson \(1980\)](#) in their major summary volume of North American Pleistocene faunas. This became the operational use that was adopted by many mammalian paleontologists in the last several decades, and also has the advantage of

defining the mammal age based on a large, recognizable, and geographically widespread taxon. Unfortunately, *Mammuthus* is absent (or rare) from some of the most important faunas that fall within the Irvingtonian interval. These include the Anza-Borrego Desert sequence in southern California (where it is rare), and the important Meade Basin faunas in Kansas (where it is conspicuously absent). Our current understanding of the time of arrival of *Mammuthus* in North America is complicated by poor external age control at many sites (reviewed by Bell et al., 2004b) that are candidates for earliest, or at least very early, appearance. Based on well-dated faunas that have unambiguous association of *Mammuthus* remains with reliable external age control, *Mammuthus* appears to have arrived and dispersed rapidly across much of the continental United States between approximately 1.3 and 1.4 Ma. Therefore, a date of 1.35 Ma for the beginning of the Irvingtonian seems acceptable.

Alternative proposals to define the Irvingtonian on the basis of various taxa of arvicoline rodents were also reviewed by Bell et al. (2004b), and may be preferable to the *Mammuthus* definition discussed above. These operational definitions are complicated by perceived faunal provinciality, resulting in provincial definitions that are based on first appearance of different taxa in different geographic areas. One consequence of this is that the Irvingtonian could be conceptualized as beginning at different times in different parts of the continent. A time-transgressive, multi-taxon definition system would complicate communication if nothing else, but a small mammal definition is unquestionably useful for the Great Plains faunas, and is used there in preference to *Mammuthus* (Martin et al., 2003). The small mammal definition now used in the Great Plains is based on the earliest appearance of the vole *Allophaiomys pliocaenicus* (also sometimes named *Microtus pliocaenicus* (see Early Pleistocene)). The temporal differences associated with alternative definitions are significant; for example, using the *Allophaiomys* definition results in a starting time of the Irvingtonian at approximately 1.9 Ma (Martin et al., 2003; Bell et al., 2004b), instead of 1.35 Ma.

Using the *Mammuthus* definition, there are only a few taxa known to be restricted to the Irvingtonian. These include the voles *Microtus llanensis*, *M. meadensis*, and *M. paroperarius*, the dog *Canis armbrusteri*, and the four-horned antelope *Tetrameryx irvingtonensis*. All of these taxa are now extinct, but there are many extant species of *Microtus* in North America. Taxa that first appear in Irvingtonian faunas and persist into the younger Rancholabrean or Holocene faunas include the opossum *Didelphis*, the pygmy rabbit *Brachylagus idahoensis*, red-backed voles of the genus *Clethrionomys*, the sagebrush vole *Lemmiscus curtatus*, the living species of muskrat *Ondatra zibethicus*, the marmots or groundhogs *Marmota flaviventris* and *M. monax*, prairie dogs *Cynomys gunnisoni* and *C. ludovicianus*, the jaguar *Panthera onca*, the saber-toothed cat *Smilodon populator*, the ermine *Mustela erminea*, the extinct skunk *Brachyprotoma*, the hog-nosed skunks *Conepatus*, the coyote and wolf *Canis latrans* and *C. lupus*, the extinct short-faced bear *Arctodus simus*, the shrub ox *Eucatherium*, mountain goats of the genus *Oreamnos*, and mammoths in the genus *Mammuthus*.

The Irvingtonian also can be divided into shorter time intervals based on the recognition of mammalian faunal change within the mammal age. The outline of a three-fold division was proposed by Schultz et al. (1978) and was subsequently

modified and expanded by Lundelius et al. (1987). It was centered on changes detected in the extensive faunal sequence preserved in the Great Plains region of the central United States. The Sappan interval spans the latest Blancan and early Irvingtonian as they are defined here. The Cudahyan was erected in recognition of transitional faunas between the earlier Sappan and later Sheridanian. Sheridanian faunas are found within normally magnetized sediments of the Brunhes Chron (Chron 1n). An alternative division is based on arvicoline rodents and was originally proposed in the late 1970s and developed extensively since that time. Traditionally, this system recognized three divisions of the Irvingtonian, numbered Irvingtonian I, II, and III, from oldest to youngest. The history of the development of this system is somewhat complex, and was reviewed extensively by Repenning (1987), Repenning et al. (1990), Bell (2000a), and Bell et al. (2004b). In the most recent revisions, new data on temporal distribution and taxonomic affinity of relevant fossils resulted in proposals that the Irvingtonian III be dropped as an undefined division. The Irvingtonian I is recognized based on the first appearance of different taxa in different regions. In the southern United States west of the Rocky Mountains, it is marked by the earliest appearance of the vole *Microtus* (Repenning, 1992) at approximately 1.4 to 1.6 Ma. In the northern United States west of the Rocky Mountains, it is marked by the earliest appearance of the heather vole *Phenacomys* at approximately 1.72 Ma. East of the Rocky Mountains, it is marked by the earliest appearance of *Allophaiomys pliocaenicus* at approximately 1.9 Ma. The Irvingtonian II is defined based on the earliest appearance, at approximately 0.85 Ma, of the voles *Microtus meadensis*, *Lasiopodomys*, and *Clethrionomys*. The Irvingtonian II extends up to the Rancholabrean, defined by the arrival of *Bison* south of 55°N latitude.

Irvingtonian mammalian faunas are distributed across much of the continental United States. Unlike the Blancan, many important Irvingtonian faunas were recovered from cave deposits. Our only records of faunal dynamics in the Appalachian region during the Irvingtonian are derived from cave deposits in Pennsylvania, Maryland, and West Virginia. The Conard Fissure deposit in Arkansas provides our only data for the Ozark region of the United States (Brown, 1908). One of the most important and taxonomically diverse Irvingtonian faunas was discovered in Porcupine Cave in central Colorado (Barnosky, 2004). The only record from the Dakotas is from Salamander Cave, and the only diverse Irvingtonian biota from the Great Basin was also recovered from a cave (Bell et al. 2004b). There are unique complications in working with Irvingtonian cave biotas, including complicated stratigraphic and depositional histories, taphonomic pathways to preservation of fossils, and problems of establishing reliable external age control. These problems are not eliminated in open-air sites, but for many of the key open-air localities in the Irvingtonian, volcanic ash beds provide a ready means for establishing the age of faunal constituents.

Non-Mammalian Vertebrate Faunal Groups

A relatively recent summary of the North American Pleistocene fish, amphibian, reptile, and bird faunas was provided by

Bell (2000b). No comprehensive synopsis of the Pleistocene fishes of North America has appeared since Miller's (1965) compilation. Literature on the group remains widely scattered, and a modern summary would be a welcome and timely addition to syntheses of Quaternary biotas.

The avian fauna also lacks a modern summary treatment. Terminal Pleistocene extinctions were reviewed by Steadman and Martin (1984), but studies of early and middle Pleistocene avifaunas are not abundant. A remarkably diverse assemblage of birds from Porcupine Cave was recently reported by Emslie (2004), who summarized additional records from the early and middle Pleistocene of the inter-mountain west.

A relatively recent review of North American Pleistocene amphibian and reptile faunas was provided by Holman (1995). He subsequently also published monographic reviews of the fossil anurans (Holman, 2003), and snakes (Holman, 2000) of North America, and these include important discussions of the early and middle Pleistocene records. In sharp contrast to the mammalian fauna during the Pleistocene, the picture that has emerged for amphibians and reptiles is one of general taxonomic and geographical stability throughout the epoch (except for the areas where continental ice sheets covered the landscape). This may in part be a result of methodological approaches used in the identification of fossil amphibian and reptile remains, but this requires further investigation (Bell et al., 2004a; Bever, 2005).

Broader Significance of Irvingtonian Biotas

The extinction of the North American large mammal fauna at the end of the Pleistocene is perhaps one of the best-known and most intensively studied aspects of faunal dynamics in the Pleistocene (MacPhee, 1999; Alroy, 1999, 2001; Barnosky et al., 2004a (see *Early Pleistocene*)). Four decades of intense research have not yielded a consensus on causal mechanisms for the extinction event that eliminated most of the large-bodied mammals on the continent. The difficulty stems from the fact that North American faunas appear to have experienced at least two major perturbations during the late Pleistocene. The first is a general climatic warming following the end of the Last Glacial Maximum. The second is the arrival of humans, with a sophisticated hunting technology. Separating the impacts of the two has proven to be difficult, and both perturbations likely played a role in the extinction (Barnosky et al., 2004a, b).

Much of what we think we know about how current global warming will affect vertebrate communities in the future is derived from studies of the late Pleistocene-Holocene transition. There is a rich record of vertebrate faunas from this transition in North America (FAUNMAP Working Group, 1994), and this record has played an important role in shaping scientific opinions regarding the potential impacts of climatic change on biotas. The strong taxonomic similarity between modern biotas and those fossilized in the Pleistocene through Holocene invites direct assessment of the impacts of climate change on the past populations of species still extant in our modern biota. As paleontologists and paleoecologists explored the fossil record over the last 60 years, it became clear that the geographical distribution and community structure

of modern species could not be taken as an accurate portrayal of their past. The discovery of Pleistocene fossils at more southerly latitudes, of species that today occupy boreal and tundra environments, soon became an accepted signature of past climatic changes. In some cases, geographic distributions in the past included apparent sympatric associations of species that today are entirely allopatric. These assemblages have no modern 'analog' and beginning in the 1940s were used (often in conjunction with stratigraphic evidence of past glacial activity) as proxy data for climatic correlations, and to interpret past glacial-interglacial cycles and their impact on faunas. The reliability, prevalence, and interpretation of these assemblages was recently questioned by Alroy (1999). Alroy's challenge was based in large part on questioning the reliability of temporal associations and possible causal relationships between climate change, the development and disintegration of no-analog assemblages, and the end-Pleistocene extinction event. The controversy here points to a fruitful area for continued research.

The record of early and middle Pleistocene vertebrates does not yet mirror that of the younger intervals of the Pleistocene and Holocene, and synthetic analysis has been hampered by apparent faunal provinciality and a relative paucity of well-dated, taxonomically diverse faunas. Nonetheless, intriguing efforts to unravel local and regional community dynamics for earlier Pleistocene times reveal that the faunal dynamics of the late Pleistocene may not be generally representative of dynamics at early warming events, even within the Pleistocene (Barnosky et al., 1996). Broad-scale comparisons that integrate and compare data sets from different time intervals have been attempted and some generalities about biotic response to climatic warming are beginning to emerge. One recent analysis of the response of mammalian faunas to four separate warming events will serve as an example (Barnosky et al., 2003). That study revealed that population density changes and phenotypic change within populations can be expected within approximately 100 years of the onset of warming. Extinction, alteration of community composition and structure, and reduction in species richness are expected as warming continues for a few thousand years. Extended warm intervals (lasting hundreds of thousands to millions of years) would be expected to lead to almost total faunal turnover. In part this would result from cumulative changes derived from shorter-term processes, and in part as a result of evolutionary responses (speciation) to new environmental conditions.

This article is reproduced from the previous edition, volume 4, pp. 3232–3249, © 2007, Elsevier B.V.

Introduction

This article gives the faunal lists, which are known from the literature, of Pleistocene large mammals from some of the better known sites in southeast Asia. Only the most important sites are discussed here, although there are clearly many more sites and caves known. However, the faunal lists from the latter are generally based on only a few species or even just a few specimens. The first problem encountered is that different authors give different faunal lists from a particular site. The basis of the lists is more or less the same, but some species, such as bovines, are differently interpreted. Furthermore, the faunal lists are in most cases based on collections made at the end of the nineteenth century and the first half of the twentieth century. These old collections were not always made under controlled stratigraphic conditions and consist of relatively a few specimens. Most of the faunal lists need an update, particularly from a taxonomic perspective.

The oldest descriptions of the faunas from a particular time slice within the sites of a particular area show that the sites have species in common, in most cases these are the larger faunal elements, such as proboscideans. However, they also show differences in species composition, mostly in the case of the cervids and smaller carnivores. This is caused principally by the fact that:

- (1) Absence of evidence was taken as evidence of absence.
- (2) There was widespread taxonomic 'splitting' and the creation of new species based on minor characters.
- (3) The material is sometimes fragmented in such a way that sound determinations could not be made, and the material can frequently be identified only to genus or family level.

In this way, the fauna of every site had its own 'set' of species, which could be termed 'local paleontology.' Thus, the presence/absence of particular species and artificial differences in comparable faunal elements in the different sites were interpreted as reflecting a chronological difference between the sites, leading to the establishment of a biostratigraphical framework. Without revisions of the material, an updated list cannot, unfortunately, be given. For this reason, the original lists are presented here, with (as far as possible) the author's reinterpretation. Some species names have been updated, like *Felis tigris* (= *Panthera tigris*), *Palaeoloxodon namadicus* (= *Elephas namadicus*) and *Euarctos kokeni* (= *Ursus thibetanus*).

Absolute dates obtained at some sites are given, but in most cases these data are under discussion. Thus, the sites are attributed broadly to the early, middle, or late Pleistocene. To have a better understanding of the region of southeast Asia, the Indian subcontinent is included.

Early-middle Pleistocene Faunas from Open Sites

Pakistan and India

The Siwalik Hills

Table 1 shows the most complete list of 'early Pleistocene' Siwalik mammals from Pinjor, made by Colbert (1935). 'Pinjor' is supposed to span Olduvai N (1.9 Ma, MIS 73–72) to Jaramillo N (1.18 Ma, MIS 35–34). The collection was assembled by Barnum Brown and most of the specimens are surface finds. This list shows clearly a mixture of (Mio) Plio-Pleistocene species and is therefore not useful for biostratigraphic purposes. In addition, the taxonomy is in clear need of updating, since many species names are synonyms. For example:

- (1) *Simia* cf. *satyrus*, which is based on one specimen. This is probably a *Sivapithecus*, but the specimen is lost. The following other specimens are noted.
- (2) *Crocota sivalensis* = *Crocota felina* = *Crocota colvini* = *Pachycrocota brevirostris* *Hyaenictis bosei* = *Thalassictis indicum* from the Mio/Pliocene.
- (3) *Pentalophodon sivalensis* = *Anancus sivalensis* (early Pleistocene).
- (4) *Archidiskodon planifrons* = *Elephas planifrons* (early Pleistocene).
- (5) *Probubalus triquetricornis* = *Hemibos triquetricornis*.
- (6) *Probubalus acuticornis* = *Hemibos acuticornis*.

The list gives a good insight into the kinds of mammals there were in the (Mio) Plio-early Pleistocene of the Siwaliks, notably *Merycopotamus dissimilis*, *Hexaprotodon sivalensis*, *Stegodon ganesa*, *Elephas hysudricus*, and *Pachycrocota brevirostris*.

Mangla-Samwal anticline (Pakistan)

The only faunal list (Table 2) based on a collection of fossils that were collected under controlled stratigraphic conditions, is from the Mangla-Samwal anticline in the Siwalik Hills, Pakistan (Hussain et al., 1992). The Mangla-Samwal anticline is located in the Jhelum re-entrant molasse basin. The oldest record of *E. planifrons* is ± 3.3 Myr BP in the Mangla-Samwal anticline, and the youngest is 2.7 Myr BP. Cervids and *E. hysudricus* first appear at the same level as the last occurrence of *E. planifrons*. The last record of *E. hysudricus* is ± 2.0 Myr BP, but this taxon may have continued for a longer period (Hussain et al., 1992). The youngest locality in the area is about 1.8 Ma old. Table 2 shows clearly that the fossils from the list of Colbert (1935) are from different levels. However, most of the taxa in the list are identified only to family or genus level, thereby limiting their use.

<i>Sus falconeri</i>		
<i>Sus cautleyi</i>		

Narmada beds (India)

Table 1 also presents the faunal list of the Narmada (Narbada) Beds (Soniaka, 1985), equally in need of updating. *H. namadicus* is a junior synonym for *H. sivalensis*. The list clearly shows Siwalik elements, such as the *Stegodon* species. The age estimations range from middle to early-late Pleistocene.

Myanmar

The faunal list of the Irrawady beds in Myanmar (**Table 1**) is based on Colbert (1943). The material was not collected under controlled stratigraphic conditions. The fauna contains typical

Based on Hussain ST, van den Bergh GD, Steensma KJ, et al. (1992) Biostratigraphy of the Plio-Pleistocene continental sediments (Upper Siwaliks) of the Mangla–Samwal Anticline, Azad Kashmir, Pakistan. *Proceedings of the Koninklijke Nederlandse Akademie van Wetenschappen, Series B* 95(1): 65–80.

Siwalik species, such as *S. insignis* and *E. hysudricus*. The presence of *Hipparion* points to an age within the Pliocene/early-early Pleistocene, whereas the *E. hysudricus* points to the middle Pleistocene. The age of this fauna assemblage should therefore be considered as (Plio?) early–middle Pleistocene.

Thailand

Nakorn Sawan

Lekagul (1949) reported *Hexaprotodon* sp., *S. ganesa*, and *Bubalus* from Nakorn Sawan, in central Thailand, where Siwalik species are again encountered. The age can be considered as early–middle Pleistocene.

Sunda Shelf – Java

The Satir fauna

The oldest fauna in Java is from Satir (Figure 1), where we find the oldest proboscidean, *Sinomastodon* (= *Tetralophodon*) *bumiajuensis*. The only other fossils, besides *S. bumiajuensis*, are a hippo, *H. simplex*, cervids, and a giant tortoise *Geochelone*. This fauna is designated as the *Tetralophodon–Geochelone* fauna. The unbalanced character of the assemblage is suggestive of island isolation. The age is considered to be early Pleistocene (de Vos and Long, 2001).

Ci Saat fauna

A younger fauna is from Ci Saat (Figure 1, in the area of Satir) and consists of *S. trigonocephalus*, *H. sivalensis*, cervids, bovines, possibly a felid *Panthera* sp. and a suid, *Sus stremmi*. The age of the fauna is considered to be late-early Pleistocene (de Vos and Long, 2001).

The Trinil HK (Haupt Knoenschicht), Kedung Brubus, and Ngandong fauna

The faunas from Trinil HK, Kedung Brubus, and Ngandong (see Figure 1 for site locations) are given in Table 3 (de Vos and Long, 2001). The faunal lists from Trinil and Kedung Brubus are based on fossils in the Dubois collection (now housed in Leiden, The Netherlands) and every fossil has been individually described. The oldest site, Trinil, became famous on account of the finding there, between 1891 and 1893, of the first fossils of *Homo erectus*. Almost all the species or subspecies of this fauna are endemic in Java.

The younger Kedung Brubus fauna comes from the locality of Dubois, situated near the village of Kedung Brubus.

The type locality of the Ngandong fauna is a fluvial terrace some 20 m above sea level near the village of Ngandong. There, several *H. erectus soloensis* skulls were found in association with mammalian remains.

The high number of bovine fossils and the low number of primate fossils point to a dry climate and an open woodland environment.

The Ci Saat, Trinil HK, Kedung Brubus, and Ngandong fauna assemblages have been designated the *Stegodon–H. erectus* fauna (de Vos and Long, 2001).

Within this faunal complex, we find the following faunal elements (although all unfortunately lack stratigraphical context): *Macaca nemestrina*, *Hystrix sgigantea*, *Caprolagus* cf. *sivalensis*, *Hemimachairodus zwierzyckii*, *Megantereon* sp., *Homotherium ultimum*, *P. pardus*, *Lutrogale robusta*, *Cuon* sp., *Nestoritherium* cf. *sivalense*, and *M. dissimilis*.

The Satir and *Stegodon–H. erectus* faunas from Java show clear affinities with the early Pleistocene faunal association from the Indian subcontinent (the Siwaliks), Myanmar, and Thailand. Five species have a direct relation with the fauna of the Siwaliks, viz., *H. sivalensis*, *P. brevirostris*, *C. cf. sivalensis*, *N. cf. sivalense*, and *M. megartereon*.

Three species from this Javan fauna are closely related to Siwalik species, viz., *S. trigonocephalus* to *S. ganesa*, *E. husudricus* to *E. hysudricus*, and *D. santeng* to the Bose-laphini. De Vos and Long, (2001) therefore concluded that

Figure 1 Map of southeast Asia indicating the position of some sites mentioned in the text and the so-called Siva-Malayan and Sino-Malayan routes.

the *Stegodon*–*H. erectus* faunal association originated from the Siwaliks and reached Java by filter dispersal via the so-called Siva-Malayan route (Figure 1). Other Asian species, such as horses and camels, in contrast, never reached Java.

This early-middle Pleistocene ecosystem, consisting of an open environment, ranged from the Indian subcontinent via Myanmar and Thailand to Java, and supported populations of *H. erectus*.

Early-middle Pleistocene Faunas from Caves or Fissure Fillings

China

South Chinese caves and fissures

Longgupo cave

The Longgupo site is located at Damiao, Wushan County, Chongqing. The cave lies 20 km south of the Yangtze River near the eastern border of Sichuan (=Szechwan) province. More than 120 species have been collected. In the middle zone of the site, early Pleistocene species such as *Sinomastodon* sp., *Equus yunnanensis*, *Nestoritherium* sp., *Ailurapoda microta*, *Miomys peii*, and an early *Homo* sp. are contained. In addition, *Gigantopithecus blacki*, *P. licenti*, *Homotherium*, and *Hystris* are also present. In contrast to the aforementioned sites where there are only dental remains, here long bones are present. The cave is well known for its stone artefacts as well as a mandible fragment and incisor, which are attributed to *Homo* sp. The age is estimated to lie within the Olduvai chron, 1.96–1.78 Myr. (Wanpo et al., 1995).

Yenchinkou

Table 4 shows the fauna list of Yenchinkou, South China (Figure 2). The list is based on fossils from limestone fissures or pits on the tops of high Paleozoic ridges, which parallel the Yangtze River in Szechwan, collected by Walter Granger during the 1920s. Granger made frequent visits along the top of the limestone ridge to purchase from the native diggers the best of the fossils procured by them (Colbert and Hooijer, 1953).

Matsumoto (Colbert and Hooijer, 1953), who described the fossils obtained by T. Sakawa, without having visiting the site, considered the Szechwan (= Sichuan) fossils as belonging to two distinct faunas, an older or ‘*Stegodon* fauna’ and a younger fauna from the ‘cave loam.’ According to Granger, this represented an ‘ecological stratification.’ The fauna was later described by Colbert and Hooijer (1953). The assemblage appears to represent a mixture of early Pleistocene elements, such as *Nestoritherium*, and Middle or late Pleistocene faunal elements, such as *Stegodon orientalis*.

The caves Liucheng, Hoshantung, Ta-hsin, Changyang, Koloshan and Hsing-an

Table 4 shows the faunal lists from Liucheng, Hoshantung, Ta-hsin, Changyang, Koloshan, and Hsing-an (Figure 2). AS.-*Ailuropoda* fauna has been described from these caves (Kahlke, 1961a, b), consisting of a combination of primitive genera (*Mastodon*, *Stegodon*) and some advanced or recent genera (*Elephas*), with animals adapted to woodland or forest environments (*Pongo*), and animals adapted to mixed or more open habitats (*Equus*). The *Stegodon*–*Ailuropoda* faunas are known from different caves, but each appears to represent a discrete time period. The fauna from one of these caves (Hoshantung; faunal composition according to Kahlke (1961b)) is generally considered to be a late part of the *Stegodon*–*Ailuropoda* fauna, dating from the late-middle Pleistocene (Kahlke, 1968) or early-late Pleistocene (Aigner, 1978), based on the presence of *Palaeoloxodon* (= *Elephas*). Within this age we can add the sites of Ta-hsin, Changyang, Koloshan, and

Table 4 South Chinese cave faunas

(?) number of specimens on which the species is based is not given.

Figure 2 Map of southeast Asia indicating the position of some sites mentioned in the text: 1 = Yenchingkuo, 2 = Koloshan, 3 = Changyang, 4 = Hsing-an, 5 = Hoshantung, 6 = Liucheng, 7 = Ta-hsin, 8 = Keo Leng, 9 = Thâm Khuyen, 10 = Thâm Hai, 11 = Hang Hum, 12 = Lang Trang, 13 = Thâm Om, 14 = Thâm Hang and Thâm P'a Loi, 15 = Thum Wiman Nakin, 16 = Thum Phra Khai Phet, 17 = Phnom Loang, 18 = Sumatran caves (Lida Ajer), 19 = Niah, 20 = Mogok, 21 = Narmada.

Hsing-an. The fauna of Liucheng Cave (see Kahlke (1961a); Table 4), is generally considered to belong to an early part of the *Stegodon*-*Ailuropoda* fauna, ranging in time from the early Pleistocene (Linghong and Lian, 1982) until the early-middle Pleistocene (Li Yanxian, 1981), based on the presence of archaic elements such as *Mastodon* sp. (represented by one isolated lower molar) and *E. yunnanensis* (also represented by one isolated tooth). The exact stratigraphical position of the fossils is not known.

Vietnam

Lang Trang Cave

The Lang Trang Caves are situated about 120 km southwest of Hanoi (Figure 2). Various very cemented 'breccias' were distinguished in the caves, and about 10,000 fossils were collected (de Vos and Long, 2001), consisting only of molars, most of which have the roots gnawed. The faunal list, given in Table 5 (de Vos and Long, 2001), is based on the description of 3250 fossils from one breccia B5 from Cave II. Although Ciochon et al. (1990) mentioned *H. cf. erectus* from this cave, *Homo* specimens have not been found. The age of Lang Trang ranges dates from >350 ka to 180 ka, that is, Middle to late

Pleistocene (Ciochon, personal communication; see Late Pleistocene of Southeast Asia).

The Thâm Khuyen, Thung Lang, Thâm Hai, Thâm Om, Hang Hum, and Keo Leng Caves

In the Thâm Khuyen Cave (Table 5), *H. erectus* apparently co-occurs with *Gigantopithecus*, and *P. pygmaeus* (Cuong, 1971; Ciochon et al., 1996). However, this must be treated with caution on account of the regular confusion of *Pongo* molars with those of hominids. The *H. erectus* molar from the site, which is illustrated by Ciochon et al. (1996), is typical of this. The site is dated 475 ± 125 ka (Ciochon et al., 1996). The fauna is similar to the one from Lang Trang. This is also valuable for the faunas excavated in the 1960s (Table 5) of Thung Lang, Thâm Hai (300–200 ka), Thâm Om, Hang Hum (=Tan Van Caves, consisting of two horizons, I and II). Hang Hum I is considered to be 80–140 ka (Cuong, 1985), Keo Leng 42–37 ka (Ciochon et al., 1996) (see for position of the sites in Figure 2). Although there are small differences in species composition of the different caves, we can be sure that we are dealing with one ecosystem, a tropical rainforest.

Laos

The caves Thâm Hang and Thâm P'a Loi

An update of the late middle Pleistocene Thâm Hang (Figure 2) fauna is given by de Vos et al. (in prep). Thâm P'a-Loi, a dozen kilometers north of Thâm-Hang, has yielded a similar fauna. In both the caves, bones are rare and porcupines have gnawed the roots of the dental elements.

Thailand

The caves Wiman Nakin and Thum Phra Khai Phet

Tougaard (1998) described the larger mammal (368) specimens from Thum Wiman Nakin and Thum Phra Khai Phet (Figure 2) in detail. Only the crowns of teeth, mostly with the roots gnawed, were recovered. The faunal list for Thum Wiman Nakin is given in Table 6. The position of the sites is given in Figure 2. The age is considered to be late-middle Pleistocene. The fauna of Thum Wiman Nakin is similar to the one from Lang Trang, with the notable presence of *Crocota*, which is unknown from the latter site.

Cambodia

The cave Phnom Loang

The faunal list from the site Phnom Loang, province of Kampot (Figure 2), is given in Table 6 (Beden and Guerin, 1973; Tougaard, 1998). The list is composed of only a few specimens, consisting only of molars. In this fauna, *P. pygmaeus* is apparently absent, although it has been reported from neighboring sites along with *Elephas* sp. and *Tapirus indicus intermedius* by Beden and Guerin (1973).

Sunda Shelf

The Sumatran caves

Table 7 shows the faunal list of the Lida Ajer Cave (see for position Figure 1) (de Vos and Long, 2001). The fauna

composition is more or less similar to the one from Lang Trang, with the exception of the absence of *Stegodon* and *Ailuropoda*. As we are dealing with thousands of fossils (again, only molars, most of which have the roots gnawed), these appear to be genuine absences. A right upper central incisor, which is semi-shovel shaped, and a left upper molar, both from Lida Ajer cave (Figure 2), were identified as *Homo sapiens* by Hooijer (1948: 182–187). All species are still extant. The age is considered to be late Pleistocene (de Vos and Long, 2001). The large quantity of orangutan indicates a humid tropical rainforest environment. The age of the Lida Ajer material date from a little more than 80 000 (Drawhorn, 1994).

The Punung Caves and Gunung Dawung

Table 7 (Storm et al., 2005) shows the faunal list of Punung (Figure 1) and Gunung Dawung, which is in the vicinity of Punung. The Punung collection of Von Koenigswald originates from two different fissure deposits and consists only of molars, in which, in most cases, the roots are gnawed. The sites were relocated in 2003 by an Indonesian–Dutch team. A new site, Gunung Dawung, was discovered and excavated. The fauna of this site is not different from the table given here (Storm et al., 2005). In the so-called Punung fauna, *H. sapiens* is present (Storm et al., 2005), because of which this fauna is indicated as the *Pongo–H. sapiens* fauna (de Vos and Long, 2001), which

is of late Pleistocene age. The large quantity of orangutan indicates a humid tropical rainforest environment.

In all the caves mentioned above (south China, Vietnam, Myanmar, Thailand, Sumatra, and Java), the fossils come from a breccia. A similar taphonomy is found. Only crowns of teeth, mostly with the roots gnawed, were recovered. The gnawing was probably caused by porcupines, which bring bones and skulls to their lairs leaving only the tooth crowns.

Borneo: Niah Cave

Medway (1979) gave a faunal list of Niah Cave material, which is dated from 40 ka (Drawhorn, 1994) until Recent. The list (Table 7) is composed of both the Pleistocene and Holocene species found in Niah. Apart from domesticated mammals (like *Canis familiaris* in the upper 6–12 inch level and *S. scrofa* dom. in the 0–24 inch level), *P. pygmaeus* in the deepest level of 102–105 inches and *Hyllobates* in the deepest level of 60–72 inches are also present. Also *H. sapiens* is present in this cave. A remarkable feature of this cave is that the fossils not only consist of molars, but also bones are present.

Based on the presence of orangutan and other elements of the tropical rainforest of the Sumatran caves, Punung, and Niah on one side, and the similar fauna of the caves from China, Vietnam, Laos, and Thailand with a similar fauna on the other side, we can deduce that during the middle and late Pleistocene there was a tropical rainforest ecosystem, running from south China, Vietnam, Laos, Thailand, and Myanmar to the islands of the Sunda Shelf. On the continent, the climate became drier and the tropical rainforest ecosystem disappeared. De Vos and Long (2001) deduced that the fauna from Sumatran Caves, Niah (Borneo), and Punung (Java) came from South China by corridor dispersal, the so-called Sino-Malayan route (Figure 1) via the Malaysian area during the late Pleistocene. One of the species that entered the Sunda region at this stage was *H. sapiens*. However, *Stegodon*, *Crocota*, and *Ailuropoda* never reached the Sunda Shelf.

Unbalanced Endemic Island Faunas

Wallacea

The many islands and seas in between Sunda and Sahul have been given the name Wallacea. In contrast to the islands of the Sunda Shelf, these islands were not connected to the mainland at times of low sea levels and show unbalanced endemic island faunas. The same is true for the Philippines.

Sulawesi

Van den Bergh et al. (2001) described the fossil record and the stratigraphic sequence for Sulawesi (Figure 1). In the late Pliocene sedimentary rocks dating to ca. 2.5 Ma, a pygmy *Stegodon* (*S. sompoensis*), a pygmy *Elephas* ('*E. celebensis*'), a strange pig, *Celebochoerus heekereeni*, and a tortoise are present. During the early Pleistocene, a large-sized *Stegodon* possibly immigrated to south Sulawesi. By the middle or late Pleistocene, both pygmy proboscideans and the tortoise had become extinct, while the large-sized *Stegodon* and *Celebochoerus* continued, or, alternatively, a new immigration of a large *Stegodon* took place. In this period, there is also a new immigration of a highly advanced *Elephas* species.

Flores

Van den Bergh et al. (2001) describe the fossil record and biostratigraphy of Flores (Figure 1). Two members are present in the so-called Ola Bula Formation: the older Member A and the younger Member B. The fossil locality of Tangi Talo in Member A contains an unbalanced endemic island fauna with the pygmy *S. sondaari*, and a tortoise *Geochelone*, which is on average much smaller than the fossil giant tortoises known from the other islands. Besides these two species, remains of *Varanus komodoensis* have been recovered from the same layer. In Member B, in the sites of Mata Menge and Boa Leza, there is another unbalanced endemic island fauna consisting of the relatively large (but still smaller-than-continental forms) *S. florensis*, the murid *H. nusatenggara*, and *V. komodoensis*. This younger fauna is associated with artefacts at the localities Mata Menge and Boa Leza, indicating the co-occurrence with humans.

Paleomagnetic dating results suggest a Late-early Pleistocene age for the Tangi Talo fauna and early-middle Pleistocene for the Mata Menge fauna (Sondaar et al., 1994), indicating an age of at least 0.7 Ma for the artefact-bearing layer. Fission track ages of stone tools by Morwood et al. (1998) date 0.88 ± 0.07 and 0.80 ± 0.07 Ma.

Timor

On Timor (Figure 1), Verhoeven (1964) discovered the first remains of a dwarf *Stegodon* at Weaiwe. The posterior part of an upper third molar of the pygmy *S. timorensis* was described and illustrated by Sartono (1969). Additional molar material from this Timor species was described and figured by Hooijer (1969), who also reported a large-sized *Stegodon* from the island, represented by a slightly worn deciduous upper third from Sadilaun. Hooijer classified this fossil as *S. timorensis* subspecies D. More material of both the dwarf and the large-sized *Stegodon* was collected during a 1970 expedition in which Hooijer participated. Hooijer (1972) described molar remains as well as postcranial elements obtained during this expedition. The stratigraphical context of the fossils, however, is not clear.

Sumba

Sartono (1979) announced the discovery of a pygmy *Stegodon* from Sumba (Figure 1). Though the stratigraphic context is not clear, the presence of a pygmy *Stegodon* suggests that Sumba was an island.

Sangihe

The small island of Sangihe (Figure 1) lies between the northern tip of north Sulawesi and the island of Mindanao of the Philippines. In 1989, F. Aziz and Shibazaki collected some stegodont material from the island, including an upper tusk and some molar remains. All material originates from the Pintareng Formation on the southeast of Sangihe Island. The age of this formation is thought to be Pleistocene (Samodra, 1989). The material was briefly described and figured by Aziz (1990) and attributed to *Stegodon* sp. B cf. *trigonocephalus*.

Philippines

Only a few mammal fossils are known and described from the Philippines (de Vos and Bautista, 2003; Figure 1). Based on the size and morphology of the molars, there is only one species of *Stegodon* present, namely *S. luzonensis* and a large species *Elephas*. *S. luzonensis* is a little smaller than the continental form. Postcranial elements reveal the presence of both a small and a large proboscidean. In addition, there is a relatively small rhino, *Rhinoceros philippinensis*, and remains of a giant tortoise (de Vos and Bautista, 2003). This faunal composition indicates clearly that it is an endemic island fauna but its stratigraphical position is not well known. Archaeological investigations by Fox and Paralta (1974) suggested that the faunal remains are of middle Pleistocene age and that at least some of the tools found are coeval with the fossils. This may reflect a similar succession to that observed in Flores: first a pygmy proboscidean and a giant tortoise, followed by a large proboscidean and artefacts.

Introduction

The late Pleistocene vertebrate record of Africa plays a key role in our understanding of human evolution and the development of modern biotic environments. Africa's large landmass and location on the equator helped support prolific radiations of large terrestrial mammals, and this past mammalian diversity has survived to modern times to a greater extent here than on other continents. Furthermore, Africa is truly the cradle of humanity, with many significant steps in human evolution occurring here, including the origins of physically and behaviorally modern humans during the late Pleistocene (see [Global Expansion 300 000–8000 Years Ago, Africa](#)). This article explores the late Pleistocene vertebrate record of Africa, spanning 126–11.5 ka, paying particular attention to large terrestrial mammals, but also considering smaller vertebrates. Because of the significance of humans in the late Pleistocene of Africa, much of what we know about the other vertebrates from this time comes from archaeological assemblages (see [Interactions with Hominids; Overview; Global Expansion 300 000–8000 Years Ago, Africa](#)). [Figure 1](#) provides the geographic location for each fossil sample discussed below, and [Table 1](#) provides the relevant references. [Table 2](#) provides the scientific names for all the species whose common names are used below.

Modern Physical and Environmental Setting

Africa's large landmass, over 30 million km² or one-fifth of the land surface of Earth, and its position straddling the equator means that it contains a diversity of habitats, which support highly diverse vertebrate communities. The continent is characterized by moderately elevated tablelands. In general, the east and south are higher, and elevation decreases moving north and west. The Atlas Mountains in the far northwest are an exception. This physical geography greatly influences the distribution of moisture, and therefore influences plant communities and ultimately the faunal communities. In general, Africa is a warm and dry continent, and patterns of rainfall largely determine vegetation patterns because of the plants' dependence on water availability ([Figure 2](#)). Annual rainfall is distributed broadly in a western pointing horseshoe-shaped pattern centered on the equator, although rainfall diminishes in the eastern highlands. For the most part, rain falls during the summer. The Cape and Mediterranean littorals are exceptions, with dry summers and wet winters creating unique ecosystems. The dominating desert, the large, extremely dry Sahara, lays to the north of this horseshoe, but deserts are also found on the African Horn and the southwestern coast. Savanna and open woodland cover about 40 percent of the continent, mainly south of the Sahara ([Turner and Antón 2004](#)). Heavy rains in

the tropical highlands create extensive river systems that bring life-giving water to otherwise dry areas. In Africa, the availability of surface drinking water is the single most limiting climatic influence for the majority of mammals ([Kingdon 1997: 449](#)).

Africa's physical geography and climate have not always been this way. Major changes caused by movements of continents and the resulting rise of mountains, rifting, and volcanoes have created profound variations in the deep past. However, glacial cycles and the related changes in sea levels and precipitation have had the greatest effect on late Pleistocene African vertebrate communities ([Link: 121, 389](#)). [Kingdon \(1997: 455\)](#) summarizes the pattern of change as occurring along two poles (see also [Adams \(1997\)](#)). During cool, dry times, arid habitats have expanded north and south, contracting again when more moisture is available; during warm, wet periods, tropical forests expanded east and west along the equator, again contracting during cooler, drier times ([Figure 2](#)). These changes have resulted in the repeated fragmentation of habitats, isolating plants and animals but ultimately increasing biodiversity.

The Fossil Records

Southern Africa

For the most part, an essentially modern fauna was in place in southern Africa by about 270 ka. This faunal community persisted until the Pleistocene to Holocene boundary 11.5 ka and is sometimes referred to as the Florisian Land Mammal Age ([Klein, 1984a](#)). However, a more precise dating of the transition from the more archaic middle mid-Pleistocene assemblages (sometimes referred to as the Cornelian Land Mammal Age) to more modern late mid-Pleistocene and late Pleistocene assemblages remains elusive (see [Mid-Pleistocene of Africa](#)), and in eastern Africa, it appears that a modern fauna was in place by 330 ka ([Potts and Deino, 1995](#)). In southern Africa, the deposits at Duinefontein 2 (DFT2) appear to straddle this transition. The upper horizon at DFT2 contains an essentially modern fauna and has been dated to ca. 270 ka using optically stimulated luminescence (OSL) (see [Optical Dating](#)). The lower horizon at the site contains an extinct alcelaphine antelope, characteristic of more archaic assemblages. OSL indicates that the sands between the two horizons accumulated 290 ka, providing a minimum age for the more archaic assemblage. The nearby site of Elandsfontein Main (EFTM) contains a very large assemblage of vertebrate remains, a high percentage of which are extinct. Among the bovids alone, when extinct subspecies are counted, 89% (16/18) of the EFTM taxa are now extinct, while only 20% (4/20) of the species in nearby late Pleistocene faunas are extinct; even when a more conservative approach is taken and only species are compared, 67% (12/18) of the EFTM species are extinct while only 14% (3/21) of the late Pleistocene species are extinct. The EFTM deposits

Figure 1 Map of the sites discussed in the text. **Table 1** provides references.

are not suitable for direct radiometric dating, so their age can be estimated only by comparing species presence and absence with East African deposits, which are more readily radiometrically dated (see [K/Ar](#) and [\$^{40}\text{Ar}/^{39}\text{Ar}\$ Dating](#)). This comparison indicates that the archaic fauna at EFTM accumulated sometime between 600 ka and 1 Ma. These results indicate that an essentially modern faunal community came into place in southern Africa sometime between 270 ka and 400 ka. After 270 ka, in the bovids, only subtle changes occurred. At DFT2, kudu horns were smaller and more tightly spiraled, and black wildebeest horns had smaller frontal bosses and failed to pass downward as they pass forward; by the late Pleistocene, the animals had evolved to more closely resemble today's animals. Once the essentially modern faunal community came into place during the late mid-Pleistocene, no extinctions of large mammals occurred until the very end of the late Pleistocene (see [Late Pleistocene Megafaunal Extinctions](#)).

Throughout southern Africa, it is possible to identify changes in mammalian faunal communities in response to late Pleistocene glacial cycles, but these changes are best documented along the southern and western coasts of South Africa, where good contextual data are available on large, well-documented faunal assemblages ([Klein, 1980](#)). The most notable aspect of the late Pleistocene faunas from this region is the overwhelming abundance of grazing species, especially alcelaphines and equids, compared to the late Holocene and historic fauna, which is dominated by browsers and mixed feeders, indicating that grasses were much more common during the late Pleistocene than at the present. This contrast is most striking at Nelson Bay Cave, on the southern coast of South Africa. The faunal assemblages from the levels spanning 18.5–12 ka are dominated by grazing ungulates, including quagga, alcelaphines, long-horned buffalo, and springbok, as well as ostrich, which also prefers open environments; none of these taxa were present in the vicinity of the site historically.

Table 2 List of the common names of animals discussed in the text, along with their scientific names

Common name	Scientific name
Mammals	Mammalia
Monkeys, apes, and allies	Primates
Human	<i>Homo sapiens</i>
Baboon	<i>Papio</i> sp.
Lemurs	Lemuridae
Bats	Chiroptera
Insectivores	Insectivora
Tenrecs	Lipotyphla
Hares, pikas, and rabbits	Lagomorpha
Cape hare	<i>Lepus capensis</i>
Scrub hare	<i>Lepus saxatilis</i>
European rabbit	<i>Oryctolagus cuniculus</i>
Rodents	Rodentia
North African crested porcupine	<i>Hystrix cristata</i>
Cape porcupine	<i>Hystrix africaeaustralis</i>
Giant gerbil*	<i>Gerbillus grandis</i>
Cape dune molerat	<i>Bathyergus suillus</i>
Common molerat	<i>Cryptomys hottentotus</i>
Carnivores	Carnivora
Dogs	Canidae
Golden jackal	<i>Canis aureus</i>

Table 2 (Continued)

Common name	Scientific name
Black-backed jackal	<i>Canis mesomelas</i>
Red fox	<i>Vulpes vulpes</i>
Hunting dog	<i>Lycan pictus</i>
Weasels, badgers, and polecats	Mustelidae
European polecat	<i>Mustela putorius</i>
Genets and civets	Viverridae
Mongoose	Herpestidae
Egyptian mongoose	<i>Herpestes ichneumon</i>
Hyenas	Hyaenidae
Striped hyena	<i>Hyaena hyaena</i>
Brown hyena	<i>Parahyaena brunnea</i>
Spotted hyena	<i>Crocuta crocuta</i>
Cats	Felidae
Wild cat	<i>Felis sylvestris</i>
Sand cat	<i>Felis margarita</i>
Serval	<i>Leptailurus serval</i>
Caracal	<i>Caracal caracal</i>
Leopard	<i>Panthera pardus</i>
Lion	<i>Panthera leo</i>
Bears	Ursidae
Brown bear	<i>Ursus arctos</i>
Fur seals and sea lions	Otariidae
Cape fur seal	<i>Arctocephalus pusillus</i>
Hyraxes	Hyracoidea
Hyrax	<i>Procavia</i> sp.
Elephants	Proboscidea
African elephant	<i>Loxodonta africana</i>
Odd-toed ungulates	Perissodactyla
Zebras, horses, and relatives	Equidae
Burchell's (plains) zebra	<i>Equus burchellii</i>
Quagga*	<i>Equus quagga</i>
Mountain zebra	<i>Equus zebra</i>
Grevy's zebra	<i>Equus grevyi</i>
Giant Cape zebra*	<i>Equus capensis</i>
Rhinoceroses	Rhinocerotidae
Black rhinoceros	<i>Diceros bicornis</i>
White rhinoceros	<i>Ceratotherium simum</i>
Merck's rhinoceros*	<i>Dicerorhinus kirchbergensis</i>
Even-toed ungulates	Artiodactyla
Hippopotamuses	Hippopotamidae
Hippopotamus	<i>Hippopotamus amphibius</i>
Madagascan hippopotamus*	<i>Hippopotamus laloumena</i>
Madagascan dwarf hippopotamus*	<i>Hippopotamus lemerlei</i>
Madagascan pygmy hippopotamus*	<i>Hexaprotodon madagascariensis</i>
Pigs and hogs	Suidae
Boar	<i>Sus scrofa</i>
Bushpig	<i>Potamochoerus larvatus</i>
Giant hog	<i>Hylochoerus meinertzhageni</i>
Warthog	<i>Phacochoerus africanus</i>
Giant warthog*	<i>Metridiochoerus/Stylochoerus</i>
Deer	Cervidae
Camels, llamas, and relatives	Camelidae
Wild camel*	<i>Camelus thomasi</i>
Giraffes and okapis	Giraffidae
Giraffe	<i>Giraffa camelopardalis</i>
Bovids, antelopes, gazelles, and relatives	Bovidae
Oxen	Bovini

(Continued)

Table 2 (Continued)

Common name	Scientific name
Cape/African buffalo	<i>Syncerus caffer</i>
Long-horned buffalo*	<i>Pelorovis antiquus</i>
Aurochs	<i>Bos primigenius</i>
Spiral-horned bovids	Tragelaphini
Bushbuck	<i>Tragelaphus scriptus</i>
Kudu	<i>Tragelaphus strepsiceros</i>
Eland	<i>Taurotragus oryx</i>
Duikers	Cephalophini
Bush duiker	<i>Sylvicapra grimmia</i>
Blue duiker	<i>Cephalophus monticola</i>
Dwarf antelopes	Neotragini
Dwarf antelope	<i>Neotragus batesi</i>
Grysbok	<i>Raphicerus melanotis</i>
Steenbok	<i>Raphicerus campestris</i>
Oribi	<i>Ourebia ourebi</i>
Reduncines and kobs	Reduncini
Mountain reedbuck	<i>Redunca fulvorufula</i>
Reedbuck	<i>Redunca redunca</i>
Lechwe	<i>Kobus leche</i>
Waterbuck	<i>Kobus ellipsiprymnus</i>
Gazelline antelopes	Antilopini
Gazelles	<i>Gazella</i> sp.
Thomson's gazelle	<i>Gazella rufifrons</i>
Springbok	<i>Antidorcas marsupialis</i>
Bond's springbok*	<i>Antidorcas bondi</i>
Southern springbok*	<i>Antidorcas australis</i>
Hartebeest, wildebeest and allies	Alcelaphini
Impala	<i>Aepyceros melampus</i>
Blesbok/bontebok	<i>Damaliscus dorcas</i>
Korrigum	<i>Damaliscus lunatus</i>
Hartebeest	<i>Alcelaphus buselaphus</i>
Giant hartebeest*	<i>Megalotragus priscus</i>
Blue wildebeest	<i>Connochaetes taurinus</i>
Black wildebeest	<i>Connochaetes gnou</i>
Horse-like antelopes	Hippotragini
Roan antelope	<i>Hippotragus equinus</i>
Sable antelope	<i>Hippotragus niger</i>
Blue antelope*	<i>Hippotragus leucophaeus</i>
Oryx	<i>Oryx gazella</i>
Sheep and goats	Caprini
Barbary sheep	<i>Ammotragus lervia</i>
Reptiles	Reptilia
Angulate tortoise	<i>Chersina angulata</i>
Spur-thighed tortoise	<i>Testudo graeca</i>
Birds	Aves
Penguin	<i>Spheniscus demersus</i>
Cormorant	<i>Phalacrocorax</i> sp.
Flightless birds	Struthioniformes (ratites)
Ostrich	<i>Struthio camelus</i>
Elephant or marsh birds*	<i>Aepyornis maximus</i>

*Indicates extinct species.

However, the dominant taxa of the younger deposits include bushpig, bushbuck, grysbok, and Cape buffalo, which also were found historically in the region of the site. A similar transition occurred at Melkoutboom Cave, located inland northeast of Nelson Bay Cave, where the terminal Pleistocene fauna was also dominated by equids (either mountain zebra or quagga or both) and alcelaphines, while the Holocene deposits resembled the modern local fauna with bushbuck, kudu, blue

duiker, grysbok, and bushpig. Again, a similar change is seen on the western coast of South Africa in Elands Bay Cave where the terminal Pleistocene fauna contains relatively more large grazers than the late Holocene component. All of these assemblages indicate that the faunal communities underwent a marked transition as environments changed from the terminal Pleistocene to the Holocene.

A similar contrast is found during the more ancient periods of the late Pleistocene at the site of Klasies River, further east along the coast from Nelson Bay Cave. Similar to Nelson Bay Cave, the historic fauna included bushpig, bushbuck, grysbok, and Cape buffalo, and also blue duiker and hartebeest. These taxa are also found in the Holocene levels of the site, as well as in the oldest deposits, which possibly correspond to oxygen isotope stage (OIS) 5e, the Last Interglacial, which began 126 ka (see [Oxygen-Isotope Stratigraphy of the Oceans](#)). As the sequence progresses through OIS 5, the relative abundance of taxa that prefer open habitats (alcelaphines and equids) fluctuates with those that prefer more closed habitats (bushbuck and grysbok). Further to the northeast at Border Cave, again a similar contrast is apparent, but the historic fauna is more characteristic of an open environment, with warthog, Burchell's zebra, and alcelaphines. These grazers are also present during the warmer times between OIS 5d and 3, but during colder times, a fauna that prefers more bush is present with bushpig, Cape buffalo, tragelaphines, and impala. Klasies River and other coastal sites also show evidence of changing sea levels and sea temperatures during the late Pleistocene, as seen in the changing abundances and taxa of marine birds and mammals, especially penguins, cormorants, and Cape fur seals. During warmer times, when the seas were higher, these animals are common, but they are rare during cold times when sea levels were lower, such as during the terminal Pleistocene at Nelson Bay Cave and Elands Bay Cave.

In the northern part of southern Africa (Namibia, Botswana, Zimbabwe, Mozambique, and Angola), less is known about the late Pleistocene faunal community. Contrasts between glacial and interglacial communities are not as clear, because the record is more sparse and because regions closer to the equator likely experienced less climatic and therefore faunal changes than southern South Africa. The late (and mid-) Pleistocene record from Zambia is better known ([Brooks, 2003](#)). Here, fossil assemblages, such as from Mumbwa Cave, closely resemble the modern faunal community with an abundance of Burchell's zebra, warthog, and alcelaphines; any deviation from the modern pattern is in the direction of adding even more grazing ungulates, such as blesbok, springbok, and mountain reedbuck, and bovids that are tied to water, such as lechwe and waterbuck. At Redcliff Cave, Zimbabwe, blesbok, springbok, and mountain reedbuck are more common during what appears to be moister conditions in OIS 2 and 4, but these animals were not documented in the region historically. In eastern South Africa, the historic and late Pleistocene faunas are dominated by grazers, but during the moister times of the late Pleistocene, lechwe, waterbuck, Cape buffalo, impala, and roan antelope appear, suggesting open woodlands were present. Blue wildebeest, sable/roan antelope, waterbuck, impala, and hartebeest in the late Pleistocene deposits of Sibudu Cave, near the coast in KwaZulu-Natal, South Africa, indicate that more open savannas existed there during ancient times than during

Figure 2 Distribution of the major vegetation zones of Africa in the present day (left) and during the Last Glacial Maximum (right). Note that under the colder, drier glacial conditions, the central forests contract east-west while the deserts expand north-south. Maps from Adams (1997) accessible at <http://www.esd.ornl.gov/ern/qen/nerc.html>.

the present. In sum, the data indicate that open grasslands were much more common in southern Africa during the late Pleistocene than they have been historically.

The above discussion has focused on bovids, equids, and suids, because these taxa are most common in the fossil record and because changes in their distributions and abundances more closely follow changes in vegetation. Carnivores have more widespread distributions than ungulates, reflecting their more generalized habitat requirements (Turpie and Crowe, 1994). Throughout the late Pleistocene of southern Africa, lions, brown and spotted hyenas, black-backed jackals, and wild cats are frequently found in fossil assemblages, along with occasional leopards, servals, caracals, hunting dogs, and a variety of mustelids and viverrids. Of the smaller mammals, typical species include baboons, hyraxes, hares, porcupines, and Cape dune moles, when the local environments are suitable. Hippopotamuses were common throughout southern and eastern Africa wherever permanent water and open grazing were available, both historically and in the late Pleistocene. Both black and white rhinoceroses make regular appearances in late Pleistocene assemblages, along with occasional elephants. Historically, giraffes were found throughout the central and northern parts of southern Africa, especially where savannas and open woodlands were common, but they are rare in the fossil record. A few examples are known, as in Florisbad and Cave of Hearths, but their chronological position of these fossils within the late mid- or late Pleistocene is unclear. The presence of giraffe in Florisbad especially indicates that past environments were very different from the historically treeless local vegetation. An example of late Pleistocene giraffe

more securely dated to OIS 3 was found in Sibudu Cave, KwaZulu-Natal, South Africa, located in an environment that has not supported giraffes in the recent past, but may have prehistorically.

In sum, the mammalian assemblages from the late Pleistocene of southern Africa closely resemble the modern-day fauna of the region, but the distribution of the taxa changed through time in response to climatic influences on vegetation. Although almost all the taxa found historically in southern Africa are seen in the fossil record, there are six exceptions: giant Cape zebras, giant warthogs, long-horned buffalo, giant hartebeest, Bond's springbok, and southern springbok (Figure 3). Although these taxa appeared throughout southern Africa during the late Pleistocene (the southern springbok appeared only on the southern and western coasts of South Africa, while Bond's springbok was everywhere else), the best sites for determining the dates of their extinctions come from the coasts of South Africa. In this region, long-horned buffalo, giant hartebeest, southern springbok, and Cape zebras are last seen between 12 and 9.5 ka (Klein, 1984b). These terminal Pleistocene dates coincide with the major environmental changes described above that occurred with the transition to the Holocene, but hunting by humans may have also played a role (global evidence reviewed in Barnosky et al. (2004)) (see *Late Pleistocene Megafaunal Extinctions*). Over-hunting by humans almost certainly caused the next set of extinctions in southern Africa: the last blue antelope was last seen around 1800 and the last-known quagga died in 1883 (Klein, 1987; Rau, 1986). However, recently studies of DNA preserved in a few of their bones and skins stored in museums have provided some data

Figure 3 Depictions of African mammals that went extinct at the end of the late Pleistocene. Drawings are courtesy of Richard G. Klein.

about their taxonomic status and phylogenetic relationships (Higuchi et al., 1984; Leonard et al., 2005; Robinson et al., 1996) (see [Ancient DNA](#)).

Compared to other regions of Africa, fossil samples from southern Africa are large enough and frequent enough to examine changes in body size within a species through time and across. This is done for two reasons. First, the average size of individuals in a species may vary in relation to temperature and precipitation, thereby being useful paleoenvironmental reconstruction. Size variation is examined between geographic locations of modern populations to understand the causes of the variation. Then these parameters can be inferred from the size of fossil specimens. This variation in size has been studied in carnivores (Klein, 1986), rock hyrax (Klein and Cruz-Uribe, 1996), Cape dune molerats (Klein, 1991), and common molerats (Avery, 2004). The second reason for studying size variation is because it may provide information about human predation pressure on a species, and from this, it is possible to infer human population densities. This has been examined using the angulate tortoise. Tortoises grow continuously throughout their lives, and if they frequently preyed upon, their median size will decrease. Studies of tortoise size from archaeological assemblages show that late Pleistocene tortoises typically were larger than Holocene tortoises (Klein and Cruz-Uribe, 1983; Steele and Klein, in press).

Northern Africa

Most of our knowledge about late Pleistocene vertebrates from northern Africa comes from coastal regions of the Maghreb, including Morocco, Algeria, Tunisia, and Libya, although Egypt is also well represented. One of the challenges to understanding the vertebrate record from this region is the lack of good chronological control. However, recent efforts to explore the late Pleistocene archaeological record of especially Morocco is changing this, and hopefully this challenge will be overcome soon. The northern African paleontological record is interesting because it contains elements of Eurasian faunas, as well as traditional African species. These immigrants include bears, cervids, and boars. The European component almost certainly entered northern Africa from the northeastern corner through what is today Egypt. An analysis of the zoogeographical affinities of mammals in the Maghreb showed that only bats were able to cross the Straits of Gibraltar and colonize from the north; all other taxa moved in from the east or crossed the Sahara from the south (Dobson and Wright, 2000).

As in southern Africa, the late Pleistocene species from northern Africa closely resemble modern species. However, it is unclear when exactly this fauna came into place, as very few reliable samples exist from the later mid-Pleistocene, when the change is documented in eastern and southern Africa (Geraads, 2002). The site of Jebel Irhoud, Morocco, lacks the later arriving cervids and boars and contains an alcelaphine with simple teeth and a large gerbil, indicating a late mid-Pleistocene age, of perhaps 150 ka (see [Mid-Pleistocene of Africa](#)). Electron spin resonance (ESR) has placed the site between 90 and 190 ka old, and it is possible that the material accumulated throughout this time span (see [Electron Spin Resonance Dating](#)). The abundance of alcelaphines, oryx, and gazelles in the sample suggests that the environment was a dry savanna. In contrast, the terminal Pleistocene and early Holocene (12–4 ka) was especially moist, and most of the mammals present in during the late Pleistocene reappeared during the Holocene, so the clear break between late Pleistocene and Holocene records, which is seen in southern Africa, is not as apparent in northern Africa. However, a few species go extinct during the Holocene, including camels, cervids, and long-horned buffalo (Klein, 1984b).

In general, the faunal remains also indicate the presence of savannas in the Maghreb during the late Pleistocene. In Haua Fteah, Libya, in Mugharet el 'Aliya and in Rhafas Cave, Morocco, and in nearby sites, the most abundant taxa are Barbary sheep, aurochs, and various gazelle, but hartebeests and equids are also present. Rhinoceroses (both white and Merck's) and elephants are also found, along with both the Cape hare and European rabbit. More rare species include porcupine, hippopotamus, deer, long-horned buffalo, eland, and blue wildebeest. Both warthogs and boar have been identified. Unfortunately, the current data available for the Maghreb do not allow us to make as detailed comparisons between glacial and interglacial cycles as in southern Africa. The fauna at Haua Fteah suggests that Barbary sheep were more abundant during drier periods and that aurochs was more abundant during wetter ones.

The carnivores of this time period are equally diverse (Aouraghe, 2000), and include golden jackals, red foxes, lions, leopards, wildcats, sand cats, caracals, spotted hyenas,

Egyptian mongooses, and European polecats. Bears and striped hyenas were also present. The bears, foxes, and polecats provide another link to Eurasian faunas that make the Maghreb's faunal community unique. Among nonmammals, spur-thighed tortoises and ostriches are also common, mirroring the assemblages often seen in southern Africa.

Late Pleistocene vertebrates are best known in northern Africa from the Maghreb, because the geology of this region allows for many deep caves, which permit good bone preservation. Unfortunately, most of the late Pleistocene sites from the eastern part of northern Africa are open-air sites, where bone is poorly preserved. What data are available, from sites such as Bir Tarfawi, Shuwikhat 1, and Makhadma 2 and 4 Egypt, indicate that the faunal communities were roughly similar between the western and eastern regions of northern Africa. Various gazelles are present, along with hartebeest, aurochs and/or long-horned buffalo. Equids, white rhinoceroses, hippopotamuses, and warthogs were also found in the east, along with porcupines, hares, and ostriches. The mix of carnivores is also similar between the two regions. The eastern region was unique because of the presence of wild camels, giraffes, and reduncines. Some assemblage also include rodents whose modern ranges are much further south in much wetter places, indicating that the fossil assemblages accumulated when the region received higher rainfall than today.

Eastern Africa

While eastern Africa has enjoyed a long history of paleontological research, most of this research has focused on the Pliocene and early Pleistocene, because these phases are associated with the hunt for early hominin fossils (see [Vertebrate Overview](#)). Recent attention on modern human origins during the late Pleistocene is changing this, but large, well-preserved, and well-dated late Pleistocene faunal assemblages remain rare.

The oldest-dated fossil assemblage in eastern Africa that contains no extinct species, essentially a modern fauna, is from Lainyamok, Kenya, and dated to about 330 ka old by Ar/Ar (see [K/Ar and \$^{40}\text{Ar}/^{39}\text{Ar}\$ Dating](#)). This date places the assemblage firmly in the mid-Pleistocene and indicates that modern species existed in eastern Africa throughout the late Pleistocene (see [Mid-Pleistocene of Africa](#)). Some nearby late Pleistocene assemblages, such as those found on Lukenya Hill, Kenya, contain the long-horned buffalo, which was also common in the late Pleistocene assemblages from southern and northern Africa, and may contain another extinct species, a small alcelaphine. However, other authors argue that these small alcelaphines are bontebok or blesbok. Blesbok also are common at Redcliff, suggesting that they once extended from South Africa through Central Africa to eastern Africa. The small alcelaphine is not found in local Holocene samples, but they are present in small numbers in Holocene samples in northern Tanzania. Oryx and Grevy's zebra are also found in the Lukenya faunas but not locally historically, suggesting that in the past, the region was more arid than today and their modern ranges were expanded to encompass Lukenya. Other common late Pleistocene species include hartebeest, wildebeest, Thomson's gazelle, and Burchell's zebra,

and mountain reedbuck, oribi, steenbok, bush duiker, and warthog are also present.

Madagascar

Although Madagascar is typically considered part of Africa, its isolation from Africa for 165 Myr and from India for 88 Myr allowed its flora and fauna to evolve along a unique path. Located almost 400 km from the coast of Africa at Mozambique, very limited faunal exchange occurred until the first humans arrived ca. 2 ka. Only ca. 100 species of mammals lived on the island before colonization by humans, and this faunal community is characterized by high endemism (about 80% of its flora and fauna are unique to the island) and taxonomic imbalance. While the mammalian community included primates (lemurs), insectivores (lipotyphlans), rodents, carnivores, hippopotamuses, and bats, very few of the typically African species ever reached the islands: no elephants, rhinoceroses, camels, giraffes, bovids, felids, or canids successfully made the crossing. Recent genetic studies indicate that most of the clades of nonvolant (nonflying) mammals to reach Madagascar did so with single colonization events, either by swimming or by rafting from Africa; lemurs arrived 62–66 Ma, and carnivores arrived later between 18 and 24 Ma ([Yoder et al., 2003, 1996](#)). However, the presence of three species of hippopotamuses, each with different ancestors, suggests that they may have arrived in three separate colonization events ([Faure and Guérin, 1990; Stuenkel, 1989](#)). Knowledge of the late Pleistocene fossil record of Madagascar is limited, but much work has been done on the subfossil record (terminal Pleistocene and Holocene), especially of lemurs, which provide an impressive example of adaptive radiation in primates. The subfossil record adds 17 extinct species to the ca. 30 still-living lemurs ([Godfrey and Jungers, 2002](#)) and allows the study of their ancient DNA, further confirming their single and ancient origin ([Karanth et al., 2005](#)) (see [Ancient DNA](#)). Among nonmammals, Madagascar was also home to giant tortoises and giant ratites (flightless birds), known as elephant birds, marsh birds, or vorompatra. These taxa probably existed on the land-mass before it broke away from Africa. The long persistence of lemurs and the other unique species on an isolated island and then their rapid and recent extinction has caused much discussion about whether their demise is related to climatic change, human hunting, or human habitat disturbance (deforestation, increased erosion, change in fire regime, introduction of new species) ([Burney, 1999; Goodman and Patterson, 1997](#)) (see [Late Pleistocene Megafaunal Extinctions](#)).

Western and Central Africa

Very little is known about the late Pleistocene vertebrate record from western and central Africa, because bone preservation tends to be poor and because few researchers have conducted paleontological and archaeological research in the region. What little evidence that is available for the region, such as found in Mbi Crater, Cameroon, indicates that during the terminal Pleistocene animals tended to be more characteristic of open habitats, with hartebeest, korrigum, roan antelope, waterbuck, warthog, reedbuck, and bush duiker being present.

Forest cover, while consistently present during the late Pleistocene, increased in the Holocene, as seen by increasing numbers of various duikers, bushbuck, dwarf antelope, bush pig, giant hog, and leopards.

Summary

Most of the mammal species found in the late Pleistocene vertebrate records of Africa were also found on the continent historically. However, many changes in the species' ranges, abundance, and associations make late Pleistocene faunal communities look different from today's communities. As the climate changed in the past, so did the vegetation. Many times in the fossil record, species are found in places where today their descendants live hundreds, if not thousands, of kilometers away, indicating that their past ranges were either completely shifted to different location or expanded to encompass new locations. Late Pleistocene climatic and vegetation changes created unique habitats, many of which do not exist today. Each species' unique responses to these dramatic changes meant that mammal communities were formed that do not have analogs today, meaning that species were often found together in fossil assemblages that are not found together historically. Only a handful of African species went extinct during the transition from the late Pleistocene to the Holocene.

Introduction

A synopsis is provided here of the late Pleistocene terrestrial vertebrate faunas of continental North America. The term ‘Pleistocene’ has a complicated early history and was originally equated to the glacial deposits in England (Bell et al., 2004). The base of the Quaternary is now set at 2.58 Ma (Gibbard and Head, 2010). Within chronostratigraphy, this system must be followed; however, overall this scheme does little to help elucidate the variations found within the changing climate (glacial–interglacial) and vertebrate faunas of the North American Pleistocene.

Subsequent to the first usage of the term, temporal relationships among the terrestrial Pleistocene deposits of North America were traditionally based on their affiliations to the classical four major glaciations (Nebraskan, Kansan, Illinoian, and Wisconsin), including interglacials between. Deep-sea sedimentary cores have shown that as many as 22 discrete glacial pulses over the past two million years are recognized (Richmond and Fullerton, 1986), which leaves the glacial and interglacial names basically useless in North America and are abandoned for use with faunal assemblages except for the most recent glaciation, Wisconsin. This glacial event retains its utility because it is within the age constraints of radiocarbon dating and is completely within the Upper or late Pleistocene. Richmond and Fullerton (1986) have the following age limitations for the Wisconsin Glaciation: ‘Eowisconsin’ (122–79 ka BP), early Wisconsin (79–65 ka BP), middle Wisconsin (65–35 ka BP), and late Wisconsin (35–10 ka BP).

A major task of a mammalian stratigrapher is to devise and operate within a framework of data that leads to the development of a succession of temporal intervals that account for all of geologic time (Woodburne, 2004). The North American Land Mammal Ages (LMAs) are constructed as biochronologic units and designed to recognize discrete intervals of time based on the evolution and association of fossil mammals (Woodburne, 2004). These units have been correlated into various geochronometric units including the Geomagnetic Polarity Time Scale (GPTS; see synopsis by Lindsay (2001)). The global standard for interpreting Pleistocene paleoclimate and chronology are the marine isotope stages (MIS), which use oxygen-isotope ratios as recorded in marine sedimentary cores. Through chronological correlation (based on additional radiometric controls and analyses), terrestrial faunas can be related and compared to these observed climatic changes.

Rancholabrean Land Mammal Age

The Pleistocene epoch contains three North American LMAs as defined in Bell et al. (2004, figure 7.3): Blancan (earliest),

Irvingtonian (early, middle, early–late), and Rancholabrean (late). The beginning of the Rancholabrean (RLB), and therefore the end of the Irvingtonian, is still inadequately understood. *Bison* (bison) is the defining taxon for the RLB. Bell et al. (2004) recognized the benefits of a single-taxon boundary definition (Woodburne, 2004), but also acknowledged the complications that seem to arise from such a definition, especially with the use of a large taxon species such as *Bison*.

The arrival time of *Bison* in North America is problematic, and therefore, the end of the Irvingtonian LMA and beginning age for the RLB is not well constrained. Until the chronology of the Irvingtonian–Rancholabrean transition can be better established, we follow Bell et al. (2004) in: (1) restricting the RLB to faunas south of 55° N latitude in North America, (2) defining the RLB by the earliest arrival of *Bison* south of this latitude, and (3) placing the best-corroborated arrival time of *Bison* (therefore the beginning of the RLB) between approximately 210 and 160 ka (i.e., late Pleistocene). Earlier dispersal events of *Bison* have been proposed; these preliminary reports of late Pliocene *Bison* in North America cannot be assessed adequately until more information is presented. Not all late Pleistocene faunas contain *Bison* and therefore their assignment to an RLB age is invariably assumed, often via a correlation with a radiometric time assignment.

Although the appearance of *Bison* defines the RLB, there are a number of taxa that are limited to just this LMA (shaded taxa in Table 1). There are a number of large and small mammals that first appear in the fossil record prior to the RLB (in most cases during the Irvingtonian LMA); some of these continue on through the RLB and some help define the end to this age (see below). Table 1 also lists some of the mammals that first appear in the RLB and continue on into the recent.

Using the definition provided by Bell et al. (2004), the RLB includes that area south of 55° N latitude, incorporating all continental USA, Mexico, southeastern Alaska, and southernmost Canada. Eastern Beringia (most of Alaska and the Yukon) is not included here because the faunas from there are characterized to be more ‘Siberian-like’ (Mammoth Steppe) than similar to the rest of temperate North America (Guthrie, 2001). Temporally, the RLB is equated, conservatively, to approximately 210–160 to 11 ka BP. This time interval would include at a minimum the entire Wisconsin Glaciation (MIS 5d-2) and the preceding interglacial (‘Sangamonian’; MIS 5e; ~130 to 115 ka BP). It remains to be determined whether or not the RLB began earlier than this (based on the arrival of *Bison*) and whether or not the age contained additional glacial and interglacial climate fluctuations and therefore concomitant alterations in the mosaic of each faunal community.

The taxa above and including *Mammuthus* are restricted to the RLB and help define the age. *Bison* is the defining species for the RLB. For more details, see Bell CJ, Lundelius EL, Barnosky AD, et al. (2004) The Blancan, Irvingtonian, and Rancholabrean mammal ages. In: Woodburne MO (ed.) *Late Cretaceous and Cenozoic Mammals of North America*, p. 232. New York: Columbia University Press.

Terrestrial Faunas

Fossil deposits of the RLB contain a diverse record of amphibians, reptiles, birds, and mammals, but certainly the most comprehensively studied are the mammals. Some of the earliest publications about these remains include those by Hay (1899) and subsequent volumes, which are still of importance. Kurtén and Anderson (1980) set the pace to understand the North American late Pleistocene mammals. There has been a recent trend to provide useful overviews and compilations of the Pleistocene vertebrates known from various states and

regions of North America (Webb et al., 2004). Such compilations provide an opportunity to update, synthesize, and simplify a large amount of information that is scattered through the literature, especially for large geographic areas. These compilations typically embrace just the mammals, but can be more geographically comprehensive and incorporate, for instance, southeastern Alaska (Heaton and Grady, 2003), Arizona (Mead et al., 2005), California (Jefferson, 1991), the Great Basin (Intermountain West) region (Grayson, 1994), Mexico (Arroyo-Cabral and Polaco, 2003), Idaho (Jefferson et al., 2002), northern North America (Harrington (2003), also includes much of the Mammoth Steppe faunas (not included here); and New Mexico (Morgan and Lucas, 2005).

The above and below references provide a good overall coverage about the North American RLB faunas but treatment is predominantly of the Wisconsin Glaciation (MIS 4–2). Little is known of the faunistics for the ‘Sangamonian’ interglacial except for what is previewed in (Pinsof 1996).

Mammals

Studies which are taxonomic in approach (e.g., *Mammuthus*, *Pampatherium*, *Desmodus*; Figure 1) are numerous and cannot be listed here; however, these can be easily located via web-based reference searches. Published investigations of morphologic variation in various mammals from the Blancan LMA, Irvingtonian, RLB, and Holocene encompass a broad range of taxa and are listed in Bell et al. (2004). Some authors have used the evolutionary changes and dispersal history of the arvicoline rodents to divide the previous LMAs (Blancan and Irvingtonian) into temporal subdivisions; however, this as yet is not possible within the RLB (Bell et al., 2004). Detailed radiocarbon dates (using accelerator mass spectrometry) on critical mammalian taxa were the key to unraveling the issue about the stratigraphic association of extant species that do not currently live together today. These currently allopatric species were found to be sympatric during certain phases of the Wisconsin Glaciation. The precision radiocarbon dating documented the contemporaneity of nonanalog species (Graham and Mead, 1987).

Figure 1 Skull of *Desmodus stocki* (extinct Stock's vampire bat) recovered from the *Nothrotheriops shastensis* (Shasta ground sloth) dung layer in Rampart Cave, western Grand Canyon, Arizona.

Amphibians, Reptiles, and Birds

Compared to research about mammalian faunas, published accounts of the RLB herpetofaunas are less common for North America. Regional compilations are rare, such as the one for the Colorado Plateau and the Great Basin (Mead and Bell, 1994) and Arizona (Mead, 2005). General overviews do exist and provide in-depth reference data sets (Holman, 1995), along with specific summaries of the anurans (Holman, 2003) and the snakes (Holman, 2000). The lizards have yet to be assessed in detail for overall North America.

A glacial climate regime did create nonanalog community scenarios for the amphibians and reptiles, as was found with the mammals. For example, the record of the cold-intolerant lizard, chuckwalla (*Sauromalus*), and the desert tortoise (*Gopherus*) in the Grand Canyon during the Wisconsin Late Glacial was used to illustrate that the climate then was more equable than today; these reptiles were found to be living in a community with juniper (*Juniperus*) and single-leaf ash (*Fraxinus*) (Graham and Mead, 1987).

No in-depth summary exists for the RLB birds, but the best available overview data set is provided by Steadman in Lundelius et al. (1983) and in Webb et al. (2004). Nonanalog scenarios for the birds are also recorded in the literature about the RLB avifauna.

Localities

A map of North America showing the location of each and every RLB locality would be of little use here; critically dated sites can be found, in part, in Graham and Mead (1987) and at the FAUNMAP website (see below). Fossil localities containing faunas of the RLB are found over the entire region. Some physiographic areas are clearly better understood than others. For instance, the intermountain west (including the Great Basin) is far less well understood than the Pacific coastal region or the karstic region of Appalachia in the eastern portion of the continent.

A project entitled FAUNMAP analyzed 2945 localities to demonstrate that the geographic ranges of individual species shifted at different times, in different directions, and at different rates in response to Late Glacial environmental fluctuations in North America (<http://www.museum.state.il.us>). They found that the modern community patterns emerged only in the most recent few thousands of years, and possibly most importantly, they determined that many Late Glacial faunal mosaics do not have a modern analog with which to compare. Much of their data set is online and can be of great use to all researchers.

Many of the RLB faunas from North America are preserved in the numerous limestone caves found throughout the continent (Figure 2), as shown in a recent book by Schubert et al. (2003). Caves typically provide snapshots of depositional history and are often biased toward select physiographic, topographic, and taphonomic settings (Harris, 2005) (Figure 3), yet they also provide extremely detailed faunal accounts and in some cases preserve organic remains often destroyed in open-air, nonpermafrost scenarios. Dry caves in the arid southwest (Figure 4) have preserved a detailed record of organic remains

Figure 2 Smith Creek Cave, Great Basin, Nevada. This classic large-entranced chamber contains millions of bones and is the type locality for Rancholabrean-age animals such a *Oreamnos harringtoni* (Harrington's extinct mountain goat), *Spizaetus willetti* (extinct eagle), and *Teratornis incredibilis* (extinct incredible teratorn).

(dung, hair, body tissues; Figures 5 and 6), which in turn provide dietary reconstructions of the extinct large mammals; examples include the Shasta ground sloth (*Nothrotheriops shastensis*; Xenarthra), Harrington mountain goat (*Oreamnos harringtoni*; Artiodactyla), shrub ox (*Euceratherium collinum*; Artiodactyla), and mammoth (*Mammuthus*; Proboscidea) (see overview in Mead and Agenbroad, 1992).

It would be extremely difficult to tally here the 'best' or 'most important' RLB localities as it would depend on the chosen criteria. For PaleoIndian localities with RLB faunas, the following sites are extremely important: Agate Basin, Blackwater Draw, Bonfire, Colby, Dent, Kimmswick, Lehner, Lubbock Lake, Murray Springs, to name but a few (Grayson and Meltzer, 2002). For dry-preserved organic remains of extinct mammals along with well-associated plant remains, one should understand the following caves: Bechan, Grobott, Rampart, Stanton's (Mead and Agenbroad, 1992). For remains preserved via permafrost, one would examine the Mammoth Steppe faunas (Harrington, 2003). For critical localities containing early *Bison* records, Bell et al. (2004, Figure 7.6) provide a list and critique. Critical RLB localities that should be understood to

Figure 3 One of many limestone caves in the Grand Canyon that preserve nests, egg shells, and feathers of Rancholabrean-age *Gymnogyps californianus* (California condor).

comprehend the full meaning of this LMA include, besides those listed above: Rancho La Brea (the type locality for the LMA), American Falls, Boney Spring, Brynjulfson Caves, Dry Cave, Camp Cady, Cheek Bend Cave, Fossil Lake, Friesenhahn Cave, Haile, Hot Springs Mammoth, Ingleside, Kennewick, Ladds Quarry, Little Box Elder Cave, Meade Basin localities, Medicine Hat, Natural Trap Cave, New Paris No. 4 Cave, Papago Springs Cave, Peccary Cave, Rainbow Beach, Reddick, San Josecito Cave, Silver Creek, Smith Creek Cave, Snake Creek Burial Cave, U-Bar Cave, Welsh Cave (references in Kurtén and Anderson (1980) and Bell et al. (2004)).

Late Pleistocene Extinction

The end of the RLB is marked by the disappearance of at least 32 genera of primarily large mammals (Table 2). The timing and cause of this extinction has been of considerable debate that began active discussion and plateaued in debate in the late 1960s through 1980s (Martin and Klein, 1984), and it still continues with great fervor. Part of the debate is whether all these mammals became extinct at the same time (an event) or if they 'slowly' died out over a period of thousands of years, possibly throughout the late Wisconsin Late Glacial (a process). A detailed examination of radiocarbon analyses directly on the

Figure 4 Bechan Cave (Utah) is a large cavern in sandstone that preserved over 300 m³ of dried dung, predominantly of *Mammuthus* (extinct mammoth) and *Eucatherium* (extinct shrubox).

critical mammal taxa has at least determined when the last of the species seems to have existed (e.g., see Mead and Agenbroad, 1992). However, this analysis does not determine when a taxon might have begun the final irreversible decline, just its apparent final demise recorded in the known fossil record.

Although it is easier to determine the time of extinction, the development of the cause is of heated debate. Two major hypotheses are established to answer or attempt to answer the cause for the terminal RLB extinction: (1) overkill at the hands of humans (directly or indirectly), and (2) environmental change.

The arrival of humans to North America is an RLB event, although the timing for this dispersal episode(s) is not precisely established. The culture utilizing the Clovis tool kit is often considered that of the first Americans (PaleoIndians) and may have arrived approximately 11,500 radiocarbon ka (Grayson and Meltzer, 2002). Yet there is still debate as to whether or not people were in South America prior to the Clovis. The Clovis event is a sudden appearance in the late RLB but it is not understood whether this was a rapid spread of a people into a new land or merely a diffusion of a new and highly distinctive stone tool technology across an extant population in the Americas. In any case, the fossil record of humans in the Americas during the RLB (and its equivalent in South America; in part, Lujanian) is extraordinary sparse.

Figure 5 Dung bolus of *Mammuthus* from Bechan Cave, Utah. Dung dates to approximately 11.600 ka BP. Note the large fragments of poorly chewed grass.

Figure 6 A preserved *Bison* (bison) keratinous hoof dating to about 13.000 ka BP from a dry cave in the Grand Canyon of Arizona.

Much has been discussed and likely will continue into the future; many critical references to this subject can be found in [Grayson and Meltzer \(2002\)](#).

The environmental change explanation for extinctions is much more complex than the overkill supposition. Whereas overkill has the direct influence of one predator (*Homo*) upon a diverse fauna occupying a multitude of communities throughout the continent, the environmental hypothesis requires the understanding the critical ecological tolerances of each taxon affected by the overall environmental changes. These climatic changes occurred presumably from the onset of deglaciation (possibly by about 18 ka BP) and lasted to (or culminated at) approximately 11 ka BP. The complexity occurs because each taxon reacts individually to climate/environmental change. Some taxa may have been adversely affected at the onset of change and became extinct early in the Late Glacial; others persisted to the end of the deglaciation. When and if there were early deglaciation extinctions is not understood and not well established, even with the existing robust radiocarbon data set. The late persistence of select large mammals is well established and their apparently synchronous timing for

Table 2 North American (southern Canada, USA, Mexico) genera and species of Rancholabrean age mammals either extinct or extirpated (†) from North America yet found living (at the generic level) on another continent

Small mammals

Chiroptera

Desmodus stocki – Stock's vampire bat

Desmodus draculae – vampire bat

Lagomorpha

Azlanolagus – rabbit

Rodentia

Cratogeomys onerosus – pocket gopher

Neotoma pygmaea – woodrat

Neotoma findleyi – woodrat

Carnivora

Bassariscus ticuti – ringtail

Brachyprotoma – short-faced skunk

?*Martes nobilis* – noble marten (*Martes americana*)

Large mammals

Xenarthra

?*Dasypus bellus* – beautiful armadillo

Eremotherium – giant ground sloth

Glyptotherium – glyptodon

Holmesina – pampathere; giant armadillo

Megalonyx jeffersoni – Jefferson's ground sloth

Nothrotheriops – Shasta ground sloth

Pampatherium – pampathere; giant armadillo

Paramylodon – mylodont ground sloth

Rodentia

Castoroides – giant beaver

† *Hydrochaeris* – capybara

Carnivora

Arctodus – short-face bear

Canis dirus – dire wolf

Homotherium – scimitar cat

Miracinonyx trumani – American cheetah

Panthera atrox – American lion

Smilodon – sabertooth

Tremarctos – bear

Proboscidea

Cuvieronius – gomphothere

Mammuthus – mammoth (many species)

Mammut – mastodon

Perissodactyla

† *Equus* – horse (many species)

† *Tapirus* – tapir

Artiodactyla

Bootherium/Symbos – muskox

Camelops – camel

Capromeryx – diminutive pronghorn

Cervalces – stag-moose

Euceratherium – shrubbox

Hemiauchenia – llama

Mylohyus – woodland peccary

Navahoceros – mountain deer

Oreamnos harringtoni – Harrington's mountain goat

?*Ovis catclawensis* – mountain sheep (*Ovis canadensis*)

Paleolama – llama

Platygonus – peccary

Stockoceros – pronghorn

Tetrameryx – pronghorn

?, there is some question as to whether or not that this is a distinct species from a living form and/or if it survived the terminal RLB extinction and persisted into the Holocene. Most genera have more than one species assigned to it but those with a significant number of species are so indicated.

extinction (in at least the greater southwest) is well established (Mead and Agenbroad, 1992). This data set has been used to support the overkill hypothesis; however, at best, it only illustrates the synchronicity of the extinction process. [Graham and Mead \(1987\)](#) provide an overview about the nature of the RLB disharmonious (nonanalog) biotas of North America that were apparently maintained by equable climates. This concept of climate effects on the biota has played heavily into the discussions about late Pleistocene, RLB, extinctions.

Mexico

Although southern Alaska and Canada, and the continental USA, are fairly well understood for their RLB faunas (especially for the mammals), it is safe to state that most of Mexico, especially northern Mexico, is basically unknown. [Arroyo-Cabral and Polaco \(2003\)](#) provide an in-depth overview of important faunas recovered from caves of Mexico, yet this covers only 15 caves and three fissure deposits for the entire country. Their publication provides the best overview (with references) about the overall RLB faunas (herps, birds, and mammals) and indicates that little is comprehensively known of this southernmost North American region. Preliminary reports occur as abstracts for annual meetings of the Society of Vertebrate Paleontology, but few data-heavy publications exist with a thorough treatment of the entire faunas (many from the central and southern regions of the country). A new locality in northeastern Sonora (bordering Arizona) is producing a wealth of remains (invertebrates, herps ([Figure 7](#)), birds, and mammals), many with a tropical ecological preference. The in-press report indicates that a tropical environment during some portion of the RLB approached the xeric and boreal communities of the southwest; it is not understood if the deposition occurred during a glacial or interglacial climatic regime. The states of Sonora and Chihuahua include the region that was the apparent ecotone between temperate USA and tropical Mexico. The lack of understanding about this region is illustrated by the creation of a faunal province to categorize

Figure 7 Teeth of *Crocodylus* (crocodile) from a marsh deposit in northeastern Sonora, Mexico, located 350 km upriver from the Gulf of California. These teeth were recovered in association with *Bison* (Rancholabrean) and many other taxa such as *Glyptotherium* (glyptodont), pampathere (extinct giant armadillo), *Tapirus* (tapir), *Cuvieronius* (gomphothere), and some of tropical affinities including *Hydrochoerus* (capibara).

the 'known' faunas. The concept of faunal provinces is discussed in [Bell et al. \(2004, p. 294\)](#) and brings to light the issues around Mexico ('limits of the Mexican faunal region are not well established or characterized'). The tropical fauna of Florida are often included within the Mexican faunal province. The FAUNMAP data confirm that the Floridian faunas were distinct from other North American faunas. Much needs to be learned about this Mexican region. A comprehensive assessment of the RLB of Mexico is sorely needed.

The Next Step

The RLB is quite well-known, yet clearly much remains to be understood, or better understood. The mammals are the best and most comprehensively understood of the terrestrial vertebrates. The amphibians and reptiles are known for some regions, some areas are better than others, while in other physiographic districts there is a total void of information. The record of the avifauna is equally as spotty and deserves more attention. These biases appear to illustrate more of a void in the number of researchers and adequate comprehensive skeleton collections and/or bias in collecting the fossils than they do some taphonomic factor in the fossil record. Screen-washing of fine sediments should be routine during excavations, no matter what the taxonomic or stratigraphic focus. Sieve sizes should be no larger than ~500 μm for screen washing in order to recover these microfossils. If the sieve sizes are on this order and screen-washing (along with sorting with the aid of a microscope) is a consistent routine, then it is certain that more information about amphibians, reptiles, and birds will emerge from fossil localities in the near future.

Vertebrate faunas are in need of better, more precise, direct chronological control. These data need to be applied to vegetational and climatic proxy data sets in order to develop a better understanding of local and regional changes. We have learned that climate is constantly changing and therefore vegetational and faunal communities were also changing, often in mosaic construct. Although constant, the magnitude of change appears to be cyclical, but not necessarily rhythmic. When possible, more dietary, molecular (DNA), and other biochemical analyses need to be conducted on or in association with the RLB taxa. Such studies should help elucidate the individual reactions to environmental change and possibly evaluate the cause for extinctions.

Acknowledgments

The author appreciates the help of Sandra L. Swift for assembling the photos used in the manuscript. Emilee Mead provided the photographs in [Figures 3, 4, and 5](#).

Scavenger: Feeding on dead animals.

Biogeographic Origin

The long history of South America (SA) as an island continent during most of the Cenozoic was viewed by Simpson (1980, p. 240), as ‘...a grand experiment in population biology, ecology, biogeography, and other subjects.’ From the late Miocene to the early Pleistocene, SA became progressively connected to North America (NA) by way of Caribbean tectonic processes. In the Pliocene–Pleistocene, the Centroamerican isthmus emerged and the acme of the Great American Biotic Interchange occurred. This terrestrial connection provided an ecologically selective dispersal corridor, where a number of animals changed their geographic distribution. This had remarkable effects on the SA fauna as northern terrestrial mammals successfully spread and diversified (Webb, in Eisenberg and Redford (1999)) (Table 1).

Late Pleistocene sediments have yielded the result of ca. 2 Myr of evolution of native SA vertebrates with the addition of NA immigrants. They include the last representatives of some indigenous and immigrant mammals that went extinct during the late Pleistocene/early Holocene (LP/EH) and diverse taxa, which successfully persist today.

Current SA vertebrate communities do not reflect that Pleistocene diversity, owing to the decimation of a considerable number of taxa (notably large turtles and large to megamammals), reflecting a tragic end to a long and fruitful trip.

Biostratigraphic Framework

The evidence from continental mammals supports the current biostratigraphic scheme, which includes the Lujanian Stage/age (late Pleistocene to early Holocene), based on the standard reference scale established by Carlos and Florentino Ameghino in late nineteenth–early twentieth centuries (Tonni and Cione, 1999). The reference area covers the Buenos Aires province and the Mesopotamian region located between the Paraná and Uruguay rivers.

Although geographic differences related to ecologic/physical processes are potential limiting factors, intracontinental correlations can still be useful. Authors usually correlate the

assemblage being studied with the typical fauna of the late Pleistocene Lujanian Stage, which includes the most typical and odd extinct SA Pleistocene mammals (glyptodonts, toxodonts, ground-sloths, etc.), some of which may have persisted into the early Holocene.

Key Sites

Geographic areas with fossiliferous sites yielding absolute ages (^{14}C : radiocarbon, TL: thermoluminescence, ESR: electron spin resonance, Th–U: uranium-series ages) and paleoenvironment/climatic interpretations are presented and briefly summarized (Figure 1; Table 2). The evidence comes predominantly from the Last Glacial Maximum (LGM) as little is known from earlier phases such as the last interglacial or from the subsequent Late Glacial interstadial.

The following information is drawn from: Hoffstetter (1952), Marshall et al. (1984), Cartelle (1994), Politis et al. (1995), Eriksen and Strauss (1998), Tonni and Cione (1999), Zárate (1999), chapters of Cartelle, Rancy, and Webb in Eisenberg and Redford (1999), Rancy (2000), Cione et al. (2003), Ficarella et al. (2003), Latrubesse (2003), Santos et al. (2003), Salemm and Miotti (2003), Iriondo et al. (2004), Alberdi and Prado (2004), Rossetti et al. (2004), Ubilla (2004) and references therein.

Northern SA (Venezuela and Colombia)

In many cases, fossiliferous sites require further research due to low stratigraphic and taxonomic resolution. Nevertheless, important sites, such as Sabana de Bogotá, Curiú, Tibitó (Colombia), Muaco, Cueva del Guácharo, and Taima-Taima (Venezuela), have yielded vertebrates including evidence of human/megafauna association. The radiocarbon dates range from 21.9 to 10.8 ka BP (Colombia), and from 16.3 to 12.4 ka BP (Venezuela) (Marshall et al., 1984; Cooke, in Eriksen and Strauss, 1998). Megafaunal mammals consumed by humans were found in Tibitó I (11.74 ka BP) and Taima-Taima (13.5–12.43 ka BP).

The climate was drier and cooler than today between 21 and 14 ka BP (6–8 °C below current values); temperature oscillations colder than today occurred at 14–10 ka BP.

Table 1 A: mammals living in SA before the Pliocene/Pleistocene interchange; B: immigrant continental mammals from NA^{a-d}

In northern Venezuela, desert-like conditions prevailed during the pleniglacial.

Andean and Western Ecuador

The open-air sites in the Interandean Depression (Quebrada Cuesaca, Pistud, and Chalán) have yielded mammalian assemblages that are unmodified by early humans. The radiocarbon dates range from 20.9 to 12.3 ka BP (see [Coltorti et al. \(1998\)](#) in [Table 2](#)). Due to an extremely arid/cold climate, the mega-fauna may have migrated to the coast ca. 12 ka BP.

Figure 1 Key sites: 1. Northern SA: a, Venezuela, b, Colombia; 2. Ecuador: a, Andean, b, western; 3. Peru: a, western, b, Andean; 4. Amazonia: a, western, b, central; 5. a, northeastern Brazil, b, central-eastern Brazil; 6. a, southern Brazil, b, Uruguay; 7. a, central Argentina and Chile, b, central-southern Chile; 8. pampean sites; 9. southern cone.

The Ecuadorian coast includes open-air sites such as San José, La Libertad (=La Carolina) and El Cautivo (Santa Elena Península), Machalilla, and Pueblo Nuevo. Amphibians, reptiles, birds, and mammals including forested and open-air taxa were found. The assemblages have been ¹⁴C-dated to 18.4 ka BP (La Carolina) and to 8.68 ka BP (El Cautivo, with mega-fauna associated with lithic artifacts) ([Ficcarelli et al., 2003](#)). The climate shifted ca. 10 ka BP from cold/arid to humid, when densely forested areas developed. Megafauna might have survived until the early Holocene in refugia, becoming extinguished largely by climatic/environmental changes.

Andean and Western Peru

Caves in the central and southern highlands (3.5–4-m altitude) (Huarco, Sanson-Machay, Uchcumachay, Pikimachay) provide good examples of the maximal altitudinal distribution reached by megafauna (glyptodonts, ground-sloths, mastodonts-like, horses). These have been radiocarbon dated from ca. 20 to 13 ka BP ([Marshall et al., 1984](#); Aldenderfer, in [Zárate, 1999](#)).

Coastal outcrops (the rich Talara-La Brea tar-seeps, Cupisnique, La Cumbre, Pampa de los Fósiles, Quebrada El Jahuay) have yielded reptiles, amphibians, birds, and mammals, including megafauna. Some of these sites have been ¹⁴C-dated from 15 to 8 ka BP ([Marshall et al., 1984](#)) and to 26–15 ka BP by uranium-series dating (see [Falgüeres et al. \(1994\)](#) in [Table 2](#)). Most of the younger ¹⁴C ages are extremely controversial (Aldenderfer, in [Zárate, 1999](#)).

As the climate shifted from cool/humid to warm/dry, the development of coastal desert may have affected the fauna. There are few, if any, instances of human/megafauna interactions, suggesting humans had an insignificant effect in local extinction of the megafauna.

Western and Central Amazonia

Western Amazonia has riverside outcrops in the rainforest (Peru, Ecuador, and Brazil) that have been radiocarbon-dated

Table 2 Examples of extinct mammals with absolute ages at late Pleistocene or early Holocene in SA. All are ^{14}C ages unless otherwise indicated

from 44 ka BP (minimum ages) to 7.9 ka BP (Latrubesse, 2003). Open landscapes, though not necessarily grassland-dominated, have been proposed for the late Pleistocene, which agrees with the opinion that the current Amazonian rainforest is not a long-established ecosystem but one that has significantly expanded during the Holocene. Megamammals indicate the presence of savanna and a dry climate in the middle/early stages of the late Pleniglacial.

Central Amazonia has yielded megafauna dated to ca. 15–11 ka BP (Rossetti et al., 2004), when gradual humidity changes occurred, causing a shift from drier to arboreal savanna ca. 11.3 ka BP and to the current dense forest ca. 4.6 ka BP.

Northeastern and Central Brazil

In this region, there are rich fossiliferous limestone travertine caves, such as Toca da Boa Vista and Gruta dos Brejões, Bahia, Lagoa Santa and Lapa do Sumidouro, Minas Gerais, and Piauí, some with over 100 km of galleries.

Inferred fossil ages and stratigraphic relationships should be treated with caution due to stratigraphic inaccuracies in the cave deposits. The following ^{14}C dates have been provided: 20.06 and 12.2 ka BP (Toca da Boa Vista and Gruta Brejões) (see Czaplewski and Cartelle, (1998) in Table 2), ca. 11 cal ka BP to a minimum age of 8 cal ka BP (Lapa do Sumidouro). While empirical evidence suggests human presence in Brazil

ca. 11–12 ka BP, and sites ca. 10 ka BP show human/megafauna coexistence (see Prous and Fogaça, (1999) in Table 2), older settlements, ca. 45–30 ka BP, are still challenged.

Mammals include extinct and living species and suggest a moister and more forested environment than today, indicating a mosaic of habitats with open and forested areas.

Uruguay and Southern Brazil

Outcrops at river and creek sides in northern Uruguay (Gutiérrez, Malo, and Sopas creeks; Cuareim river) are rich in extant and extinct vertebrates, dominated by mammals and biostratigraphically correlated with the Lujanian Stage. There are radiocarbon dates at 11–12 ka BP and ranging up to >43 ka BP (minimum ages), whereas TL has produced age estimates of 43 and 58 ka BP (Ubilla and Perea in Tonni and Cioni, 1999; Ubilla et al. in Iriondo et al., 2004). The vertebrates are indicative of various habitats and tropical/temperate taxa suggest different climatic conditions compared to the typical Lujanian fauna, which was greatly influenced by the LGM. Sites in southern Uruguay (Santa Lucía river) have yielded vertebrates including megafauna and the radiocarbon dates range from 10.5 to 11.5 ka BP. However, there is no apparent association between megafauna and cultural remains in archaeological sites between 11.2 and 9.5 ka BP (Suárez and López, in Salemme and Miotti, 2003).

In Rio Grande do Sul (southern Brazil), open-air sites alongside rivers and creeks have predominantly yielded mammals, zoogeographically correlated with the Lujanian fauna. These have been dated by ^{14}C and TL from 8 to 30 ka BP (Oliveira in Tonni and Cione, 1999; Ubilla, 2004). Sites with mammals characteristic of tropical areas suggest a temperate/warm climate. In contrast, other localities have produced an austral fauna related to a dry/cold climate.

Grasslands dominated the southern Brazilian landscapes during the late Pleistocene when savanna and dry forest were replaced by grassland and subtropical gallery forest.

Central Argentina and Central-Southern Chile

Open-air and rock-shelter sites (Gruta del Indio, central Argentina; Quereo, Tagua-Tagua, central Chile; Monte Verde, central-southern Chile) provide both remarkable information about the early peopling of SA and important evidence concerning human predation on megafauna (mastodon-like, camelids). The radiocarbon dates range from ca. 30.8 to 8 ka BP and early human settlement could have occurred ca. 13 ka BP (Monte Verde) (Marshall et al., 1984; Borrero in Zárate, 1999; Alberdi and Prado, 2004). The paleozoogeographic differences with pampean Lujanian fauna were created by geographic isolation because of the Andean altitude.

A climatic shift from cold/wet to dry has been observed. This, along with human predation in central Chile, might have triggered the local megafauna extinction.

Pampean Area (Central-Eastern Argentina)

Sites on the flat grasslands have produced typical Lujanian fauna (Paso Otero, Quequén Salado, Tres Arroyos, Lobería, Luján River, etc.). There are many ^{14}C dates ranging from 29 to ca. 4.3 ka BP (Cione et al., 2003, and references therein; Table 2).

A cold and arid climate would have predominated during the late Pleistocene. Nevertheless, ca. 29 ka BP, the mammals indicate the presence of a warm/humid climate. In contrast, colder and more arid conditions prevailed from 18 to 10 ka BP due to the influence of the LGM, as witnessed in the vertebrate record from the cold/arid central Patagonian region. A replacement of dry steppe by humid grassland suggests a change from a subhumid to humid climate at the LP/EH boundary.

Relevant sites (Arroyo Seco, La Moderna, Cerro La China, Cueva Tixi cave) provide valuable information on the megafauna/human relationship. Radiocarbon dating of these sites spans the period 12.35–6.5 ka BP (Politis et al., 1995; Borrero et al. in Eriksen and Strauss, 1998). Despite criticisms of some of the youngest ^{14}C ages (see Table 2), it is likely that extinct mammals (glyptodonts, horses, and perhaps ground-sloths) were consumed by humans also in the early Holocene. Consequently, in the pampean area, early hunter-gatherers could have had more of an impact on megafaunal extinction than in the higher latitudes.

South American Southern Cone (Argentina and Chile)

Caves and open-air sites in southern Patagonia and Tierra del Fuego have yielded many paleontological and archaeological

assemblages: Cueva del Mylodon, Fell's, Palli Aike, De Los Chingues, Lago Sofia, and Del Medio caves and the rock shelter Tres Arroyos (southern Chile), and Las Buitreras Cave, Los Toldos, and Piedra Museo (southern Argentina). These sites have been ^{14}C -dated from 13.2 to 8.5 ka BP (Borrero et al., in Eriksen and Strauss, 1998; Alberdi and Prado, 2004). Birds and mammals, including megafauna, predominate. Despite having latitudinal differences, there are paleozoogeographic similarities between the western southern fauna and the pampean Lujanian one that were likely facilitated by areas of low Andean altitude.

These sites shed light on issues concerning high-latitude SA megafaunal extinction. Nevertheless, more geoarchaeological/taphonomic studies and first appearance datum analyses need to be performed in order to more precisely assess patterns of predation by humans.

There is no conclusive evidence that megafauna persisted into the Holocene, but those confidently dated to 13–12 ka BP are in general unassociated with humans (see Late Pleistocene Megafaunal Extinctions).

Horse and camel bones show evidence of human consumption, but if humans definitively occupied the southern cone by 11 ka BP, the interaction could have been no longer than 500 yr.

Before 11 ka BP, xeric scrub-steppe developed. Later, ca. 11–10 ka BP grassland including swamps, ponds, and flood-plains predominated under an arid/cold to humid/cold climate.

Fauna

A selected set of late Pleistocene SA taxa (predominantly mammals) is presented. Due to taxonomic controversy concerning many taxa, the most commonly used nomenclature is given.

The following information is compiled from: Marshall et al. (1984), Cartelle (1994), Alberdi et al. (1995), Arratia (1996), Tonni and Cione (1999), chapters of Cartelle and Rancy in Eisenberg and Redford (1999), Vrba and Schaller (2000), Bond et al. (2001), Croft (2001), Pardiñas et al. (2002), Bargo (2003), Cione et al. (2003), Alberdi and Prado (2004), Guerin and Faure (2004), Soibelzon et al. (2005), MacFadden (2005), Prado et al. (2005) and references therein. Paleobiological and anatomical reconstructions were created by G. Lecuona.

Chelonia

Large turtles (*Chelonoides*), the equivalent in size to Galapagos tortoises but with a thicker carapace, were widespread in SA and died out in the late Pleistocene. Despite being conspicuous in terrestrial vertebrate communities, unfortunately, their paleobiology and taxonomy are elusive (Figure 2).

Aves

In the Pampean region, avian fossils mostly belong to extant species. Nevertheless, an extinct rhea (*Rhea fossilis*) (Figure 3(a)), more slender than the recent ones, was probably widespread outside the pampas in lowland open country landscapes of SA. These flightless birds inhabited grasslands and also scrub forest and are useful paleoecological indicators.

Figure 2 Large terrestrial extinct turtles: *Chelonoides* (northern Uruguay). Photograph: Lecuona, G.

Figure 3 (a) An extinct rheid (flightless bird) from the pampas (*R. fossilis*); (b) large extinct monkey *P. brasiliensis* (Bahia State, Brazil).

In the Talara tar-seeps (coastal Peru), a rich assemblage of birds including tinamous, grebes, cormorants, storks, cranes, ducks, falcons, egrets, and lapwings was found.

Mammalia

Primates

There are remarkable records of two extinct ateline monkeys in Brazilian caves.

Protopithecus brasiliensis, at 25 kg in weight, more than twice the size of living SA monkeys, possessed a unique combination of cranial howler alouattine features (modified for an enlarged vocal sac) with postcranial spider and woolly spider ateline adaptations (for suspensory posture and a brachiating mode of locomotion) (Figures 3(b) and 4). *Caipora bambuiorum*, also bigger than recent atelines (>20 kg), is similar to spider-monkeys (without vocal sac).

Both required closed forest and suggest a more prominent expansion of forest in the late Pleistocene than exists today in northeast Brazil.

Xenarthra

These are a peculiar mammal group, including forms still living in SA, with remarkable features such as extra-articular surfaces in the backbone, few or no incisors, absent canines, cheek-tooth enamel usually absent, and bizarre fossil types. Xenarthrans include anteaters, tree- and ground-sloths, glyptodonts, and armadillos. The LP/EH extinction decimated mostly the strangest forms.

Glyptodonts

These armadillo-like animals were armored and tank-like, with a dorsal bony helmet, three-lobate straight and ever-growing grinding teeth, a bony rigid carapace (made of polygonal plates

Figure 4 Large extinct monkey *P. brasiliensis* (Bahia State, Brazil). Photograph: Cartelle, C. (Universidade Federal Minas Gerais-Brazil). Adapted from Cartelle (1994), page 84, with permission.

with surface designs that are taxon specific and therefore useful diagnostic characters) at the top and sides of the body, and an armored tail usually composed of rings and with a club-like end (Figures 5 and 6). The glyptodonts became extinct in the LP/EH, they were probably open-country grazers, and well-known species ranged in weight from 300 to 1500 kg.

Glyptodon clavipes, with an entirely ringed tail, is a frequent Lujanian megamammal along with *Panochthus tuberculatus*, with a clubbed tail (Figures 5(a), (b), 6(a), and (b)); *Doedicurus clavicaudatus*, one of the largest glyptodonts, with spikes in tail, was exploited by humans in the pampean region.

Armadillos and armadillo-like pampatheres

Successful xenarthrans are represented today by only nine armadillo genera, ranging from small- to large-sized (0.450–60 kg) and inhabiting both open and forested areas. Armadillos are diggers, scratchers, and are generally omnivorous. The carapace is not rigid as in glyptodonts; they have cephalic, shoulder, and hip shields constituted of bony scutes with movable bands in between. *Eutatus seguini*, a large armadillo (ca. 50 kg), disappeared in the LP/EH; *Propraopus*, a digger (ca. 50 kg) with a wide geographic distribution, went extinct in the late Pleistocene.

Figure 5 Late Pleistocene xenarthrans: (a) *P. tuberculatus* and (b) *G. clavipes* (southern Uruguay); (c) *P. humboldti* (northern Uruguay); (d) *L. armatus* (southern Uruguay); (e) *M. darwini* (Argentina); (f) *G. robustum* (southern Uruguay); (g) *E. laurillardii* (Minas Gerais, Brazil); (h) *M. americanum* (Argentina). Upper scale: (a–c); lower scale: (d–h) Photographs: a, b, d, f, h: Lecuona, G.; C: Ubilla, M.; E: Rinderknecht, A.; G: Cartelle, C. (UFMG-Brazil).

Figure 7 Late Pleistocene xenarthrans: *P. humboldti* (Brazil). Photograph: Ubilla, M.

The Pampatheres may be an intermediate group between armadillos and glyptodonts. They were large herbivorous animals (ca. 200 kg) and were predominantly grazers. Taxa such as *Pampatherium* and *Holmesina* measured more than 1 m in length. They spread across SA and became extinct in the LP/EH (Figures 5(c), 6(c), and 7).

Ground-sloths

Though only tree-sloths (4–9 kg) live today in the tropical forest zones of SA, the curious and intriguing large to mega-ground-sloths, clearly different from each other in their cranial morphologies, were successful in SA: *Nothrotherium maquinense*, *Scelidotherium leptocephalum*, *Glossotherium robustum*, *Myiodon darwini*, *Lestodon armatus*, and the giants *Megatherium*

Figure 8 Ground-sloths: (a) *G. robustum*; (b) *M. americanum*; (c) *E. laurillardi*.

americanum and *Eremotherium laurillardi* (Figures 5(d)–(h) and 8). They ranged from 50 to ca. 10 000 kg of body mass and could have been bipedal. Ground-sloths had hair instead of a carapace and some had round ossicles embedded in the skin.

The morphological differentiation suggests a niche partitioning based on size, habitat, or diet. Traditionally viewed as clumsy, mostly browsing mammals, new interpretations suggest that they might have been more active, encompassing diggers (*S. leptocephalum*), grazers (*G. robustum*, *L. armatus*), mixed feeders (*Myiodon darwini*), and browsers (*S. leptocephalum*, *M. americanum*). All ground-sloths were wiped out in the LP/EH and *Megatherium* may have been preyed by humans in the pampean region.

Litopterna

Two families of this ancient and extinct SA ungulate group persisted in the late Pleistocene.

Macrauchenids

The large litopterns, a group of strange herbivores reminiscent of camels, originated in the SA Tertiary. *Macrauchenia patachonica* (ca. 1000 kg), the best-known late Pleistocene macrauchenid, became extinct in the LP/EH. It had relatively low-crowned teeth and stocky limbs with three functional toes; due to its elongated neck, it is usually reconstructed as similar to the extant giraffe. Over its long snout, the nasal bones were vestigial and nasal openings were located far back on the top of skull, which has led to an unresolved discussion over the presence of a proboscis (Figures 9(a), 10(a) and (b)). *Macrauchenia* could have been a mixed feeder. Traditionally thought of as amphibious, it is today considered to be a cursorial terrestrial mammal. It was widespread in the highland and

Figure 9 SA ungulates: (a) *M. patachonica* (Argentina). (b) *X. bahiense* (Brazil). Adapted from Cartelle (1994), page 96, with permission. (c) *T. platensis* (southern Uruguay). Photographs: (A) Reguero, M. (Museo de La Plata, Argentina); (B) Cartelle, (C) (UFMG-Brazil); (C) Lecuona, G.

lowland zones of SA and could have occupied diverse biotopes. *Xenorhinotherium bahiense* (Figure 9(b)), a slightly smaller close relative of *M. patachonica*, inhabited the intertropical landscapes of SA.

Figure 10 Southern ungulates: (a, b) *M. patachonica*, reconstructed without proboscis. (c) Proterotheres *N. recens*. Notoungulate: (d) *T. platensis*.

Proterotheres

Small- to medium-sized cursorial litopterns range in size from a rabbit to peccaries. They show a horse-like tendency to monodactyly and were commonly used as an example of an inadaptable limb pattern. Although 16 proterotheres genera diversified in the SA Tertiary, only one straggler persisted in the Pleistocene – *Neolicaphrium recens* (Figure 10(c)). The proterotheres were not an iteration of an ecological Holarctic group such as equids, but were a southern ‘evolutionary experiment,’ convergent with horses in their monodactyl condition and probably confined to a few warm forested relict microhabitats (Mesopotamian Argentina and Uruguay). The extinction of *N. recens* was apparently unrelated to the immigration of NA ungulates.

Notoungulata

Notoungulates were a group of highly diverse ungulates in the SA Tertiary, but during the late Pleistocene the diversity reduced, leaving only *Toxodon* and its relative *Mixotoxodon* to persist into early–middle Holocene (see Table 2).

T. platensis, the best-known species in Lujanian age, was a large and heavily built megaherbivore (ca. 2000 kg), a hippo- or rhino-like mammal with short nasal bones in a heavy skull (Figures 9(c) and 10(d)). Its short, stocky, and almost graviportal legs had three-hoofed toes. It possessed chisel-like incisors and rootless, permanently growing and high-crowned molars. It was widespread mainly in the eastern Andean lowland and, on account of its hippo-like aspect, was traditionally considered semiaquatic. Nevertheless, reappraisal of its postcranial morphology suggests a terrestrial open-country mode of life.

Despite having the morphological adaptations of an open-country grazer, stable isotope studies of dental enamel indicate

a broad range of dietary adaptations according to latitudinal local vegetation: forest browser (Amazonian), mixed feeder (Argentina and Brazil, Bahia State), to grazer (Chaco, Bolivia). Consequently, according to their principal food source, *Toxodon* could have inhabited different habitats.

Rodentia

Caviomorph rodents are represented by several taxa (Table 1), mostly extant. It is noticeable that the large extinct capybara *Nechoerus*, which was widespread over most of SA, is closely related but ca. 40% larger than the largest living rodent *Hydrochoerus*, weighing ca. 90 kg. A large and extinct porcupine (*Coendu magnus*) has been found in Brazil, Bolivia, and Uruguay (Figure 11); there are also extinct species of caviines, mainly found in the arid/semiarid landscapes of southern SA.

A considerable number of sigmodontine rodents, useful as ecological indicators, were found in SA including few extinct species (pampean area and northern Argentina; Talara, Perú; Tarija, Bolivia; and Lagoa Santa, Brazil).

Figure 11 Caviomorph rodents: *C. magnus* (Bahia, Brazil). Photograph: Ubilla, M.

Perissodactyla

Two lineages of ungulate mammals with a mesaxonic (i.e., having a central toe much enlarged that bears the weight) foot reached SA: horses and tapirs. Three species of tapir survive today in the tropical/temperate landscapes of SA but horses disappeared at the LP/EH boundary.

Horses

Two genera inhabited SA: *Hippidion* (three species; 250–460 kg), an endemic Pleistocene horse, and *Equus* (*Amerhippus*) (five species; 220–380 kg). The last genus, already well-established, colonized SA during the middle Pleistocene. Both genera of horses were robust and had comparatively large heads relative to their bodies.

Hippidion, aside from a different dental morphology, is characterized by retracted and stylized long nasal passages that clearly differentiate it from *Equus* (*Amerhippus*) (Figures 12, 13(a), and (b)).

Both developed similar ecological morphotypes (small species were presumably adapted to savannas, high-latitude areas, and mountain valleys, and large ones inhabited savannas) but *Equus* (*Amerhippus*) could have been more cursorial. Dental chemistry reveals that *Hippidion* was a mixed feeder and *Equus* (*Amerhippus*) predominantly a grazer to mixed feeder.

The small horse, *H. saldiasi*, frequently found in archaeological sites of southern SA, exhibits clear evidence of human predation.

Tapirs

Little is known about late Pleistocene tapirs in SA and remains are usually identified as *Tapirus terrestris*, the most widespread species in SA. Nevertheless, the diversity is likely underestimated; further fieldwork and better records may improve their taxonomic status and knowledge of their paleoecological adaptations at different latitudes. Today, modern tapirs live up to 28° S but in the late Quaternary they reached ca. 32°–35° S (pampean area and Uruguay).

Figure 13 Horses: (a) *Hippidion principale*; (b) *E. (A.) neogeus*. Carnivore: (c) *Smilodon populator*.

Carnivora

Carnivora are represented in SA by a variety of successful small to large-sized immigrant mammals, that were mainly terrestrial but secondarily aquatic. These animals usually bore large canines and ranged in dietary adaptations from predominantly omnivorous to strictly carnivorous. Though the late Pleistocene extinction affected some taxa, they are conspicuous members of current mammal communities (cats, bears, foxes, raccoons, river otters, skunks).

Bears

SA bears differ from other bears in having short faces. The small spectacled bear (*Tremarctos*) only survives today in the northern-central mountains. In contrast, three species of medium-large-sized *Arctotherium* (300–700 kg) were present during the late Pleistocene. They were presumably carnivorous and/or omnivorous, were widespread over SA, and went extinct in the early Holocene.

Cats

Small to large felids, including the mountain lion (*Puma*) and the jaguar (*Panthera*), the largest predator in SA, were widespread in different highland and lowland habitats in the late Pleistocene and in recent times.

An extinct felid (ca. 400 kg), the saber-tooth *Smilodon populator*, possessed large blade-like upper canines in a broad muzzle (Figures 13(c) and 14(a)). It spread over most of SA and is generally considered a predator. Nevertheless, a different opinion claims a scavenging habit based on the premise that a functional constraint of the blade-like canine would not allow the bite of a proper predator.

Artiodactyla

NA immigrant ungulates with paraxonic arrangements of the foot (i.e. with the third and fourth metapodials larger than the others and bearing most of the weight) are represented in late Quaternary sites by three different families (deer, camels, and peccaries), which successfully diversified and became widespread in highland and lowland landscapes. Although some taxa disappeared in the late Pleistocene, they are still part of the modern mammal communities of SA.

Peccaries

The two genera living in SA today have a stocky body, relatively slender limbs, and are omnivorous. *Tayassu* (two species) are widespread over most of SA in diverse habitats; *Catagonus* (one species), the largest, is endemic of the Chaco (Argentina, Paraguay, and Bolivia), and inhabits semiarid xerophytic woodlands and thorn forests in a dry/warm climate. *Catagonus* and related forms have been recorded from Brazil, Uruguay, and Argentina. *Brasiliuchoerus stenocephalus*, from the caves of Brazil, is an extinct peccary close to *Catagonus* with a long and narrow snout (Figures 14(b) and 15(b)).

Camels (guanacos and vicuñas)

These are medium- to large-sized artiodactyls with a long neck and two toes in their lower limbs. Today, they live in arid/semiarid regions. The mixed-feeder guanaco (*Lama guanicoe*) (45–96 kg) is found at elevations ranging from sea level to 5 000 m in southern/western SA, and the grazer vicuña (*Vicugna vicugna*) (30–65 kg) occurs in the rolling grasslands and plains of highland Andean landscapes (3500–5700 m; Peru, Bolivia, and Chile). In the late Pleistocene, they were represented by more taxa and were widespread over most of SA including the intertropical and pampean lowlands, thereby

Figure 15 Gomphotheriid: (a) *S. platensis*. Artiodactyls: (b) *B. stenocephalus*; (c) *Hemiauchenia*.

suggesting that the current highland distribution is a secondary adaptation.

Large guanacos were also present during the late Pleistocene: the cursorial grazer *Hemiauchenia* (Figure 15(c)) and the likely browser *Paleolama* (ca. 400 kg) in the highland and lowland zones became extinct in the LP/EH. *Lama gracilis*, an extinct open-country grazer, intermediate in size between the guanaco and the vicuña, was described from pampean area. The presence of the guanaco in Amazonia and northeastern Brazil is remarkable and unexpected.

Extinct and extant SA camels were predated by humans in the LP/EH (Chile and Argentina).

Deer

The deer underwent an explosive radiation in SA occupying a broad range of habitats in the lowlands and highlands. They are mostly represented in sites by antlers and sometimes dominate the record (see sites of northern Uruguay in the

Figure 16 NA invaders. Gomphotheriids: *S. waringi* (Quebrada Pistud, Ecuador). Photograph: Marco Ferretti (Museo di Storia Naturale, Università di Firenze, Italy).

late Pleistocene). Living genera have been reported in the late Pleistocene (*Pudu*, *Odocoileus*, *Mazama*, *Ozotoceros*, *Blastoceros*, *Hippocamelus*), ranging from the dwarf *Pudu* (9 kg) to the large *Blastoceros* (ca. 100 kg). Extinct taxa such as the large *Antifer* and medium-sized *Morenelaphus* and *Paraceros* (Figure 14(c)) contributed to the largest diversity of herbivorous artiodactyls in SA.

Proboscidea

Two gomphother genera, derived from a NA lineage, inhabited SA and became extinct in the late Pleistocene. *Cuvieronius* (one species) was small and distributed in Andean landscapes, whereas *Stegomastodon* (two species) was larger and was widespread, mainly in the lowlands. These megaherbivores had a short skull and mandible, with elongate upper tusks (Figures 15(a) and 16).

Cuvieronius might have been a mixed feeder in cold/temperate climates; *Stegomastodon*, mostly related to warm/temperate climates, could have had a broader range of dietary preferences (browser to grazer) according to its altitudinal/latitudinal distribution.

Humans utilized gomphotheres as a food source in Venezuela, Colombia, and Chile.

LGM Effect

Regardless of the fact that the cone shape of SA might have affected the timing of the LGM cooling, it is possible to confidently demonstrate some vertebrate responses to the following major processes:

1. Lowland landscapes at low/median latitudes underwent climatic/geographic changes in the middle and late pleni-glacial. Despite there being a controversy over the effect of the LGM in the Amazonian forest, there is empirical evidence that open-country mammals (guanacos, glyptodonts, macrauchenids) colonized intertropical areas (Cartelle in Eisenberg and Redford, 1999; Latrubesse, 2003).
2. A severe aridification and cooling occurred both in the highlands and in the lowlands at different latitudes. Megamammals migrated from the Ecuadorian highlands to the lowlands (Ficcarelli et al., 2003). Aridification, cooling, and an expansion of open ground promoted a south–north shifting of cold/arid and open landscape. ‘Southern taxa’

such as the Patagonian rhea *Pterocnemia*, the marsupial *Lestodelphis*, rodents such as *Dolichotis patagonum* and *Microcavia*, and the guanaco *L. guanicoe* were reported in pampean landscapes (Cione et al., 2003).

3. The post-LGM warming caused a modification of a range of megamammals and favored survival or expansion of forest fauna (Cione et al., 2003).

Table 3 Some large and megamammals that became extinct in SA at the late Pleistocene and LP/EH boundary

Order XENARTHRA	Order NOTOUNGULATA

South American LP/EH Extinction

In contrast to Africa, where megafauna are still alive, in SA 80% of large mammals weighing over 45 kg and 100% of megamammals (>1 000 kg in weight), giant turtles, and some medium-sized mammals became extinct at the LP/EH boundary (Table 3; see [Late Pleistocene Megafaunal Extinctions](#)). Both immigrant and native mammals (mostly xenarthrans), adapted or presumably adapted to open landscapes, comprising ca. 50 genera of the large Lujanian fauna, died out. The few surviving large mammals (14 species) are predominantly adapted to forest, highlands, and wetlands. The causes of extinction in SA are still debated and many factors are invoked ([Cione et al., 2003](#); [Alberdi and Prado, 2004](#)).

Only the large and megamammal extinctions seem to correlate with climatic or environmental changes, and the larger the animal, the more susceptible it was ([Alberdi and Prado, 2004](#)).

Humans certainly hunted horses, mastodon-like pachyderms, large camelids, some glyptodonts, and ground sloths in some parts of SA. Although it is unlikely that human predation was the sole cause of extinction of all large/megafauna, it may have reduced population sizes of some large/megamammals, particularly in extreme environmental conditions.

Late Pleistocene of Southeast Asia

Y Chaimanee, University of Poitiers, Poitiers, France

© 2013 Elsevier B.V. All rights reserved.

This article is reproduced from the previous edition, volume 4, pp. 3189–3197, © 2007, Elsevier B.V.

Introduction

The late Pleistocene period begins 126 ka with the base of the Eemian interglacial stage, corresponding to the base of marine oxygen isotopic substage 5e. It also includes the last glacial episode of the Pleistocene and ends with the beginning of the Holocene, 11.5 ka. Due to high amplitude climatic fluctuations induced by cyclical glaciations alternating with interstadials, this period represents a key for the understanding of the distribution and composition of extant mammalian communities and for the evolution of modern humans, *Homo sapiens*.

Biogeography of Southeast Asia

Today, two biogeographic provinces are distinguished in Southeast Asia. The Indochinese Province or Northern Province includes many mammals that do not extend west into India or north into temperate China, but some extend southward, as far as Malaysia and the Greater Sunda Islands. The Sundaic or Southern Province contains many endemic genera (Corbet and Hill, 1992). The boundary between these two provinces is located at the Isthmus of Kra in Thailand, at about 10° 30' N (Figure 1). This boundary was initially based upon vegetation changes with evergreen rainforest in the south and more seasonal forest in the north. Most animal species' distributions are affected by this boundary, but its importance varies according to the different taxonomic groups. The mammalian boundary is also located slightly north of the Isthmus of Kra (Tougaard, 2001; Woodruff, 2003). A cluster analysis by Tougaard (2001) indicated that large mammal faunas of Thailand north of Kra Isthmus group with those of the Indochinese Province, whereas faunas south of Kra Isthmus group with those of the Sundaic Province. This was initially demonstrated by Chaimanee (1998) for rodents, which show a more significant change at the Kra Isthmus than large mammals.

Southeast Asia has undergone dramatic climatic and geographic changes during the Pleistocene. It is supposed to have been significantly drier and cooler with more seasonal climates during glacial periods (An, 2000). These climatic oscillations are associated with repeated shrinking and expansion of rainforests and correlative spreading and shrinking of savannas. According to Morley (2000), pine woodlands and savanna grasslands expanded and replaced the rainforest over large areas of Southeast Asia during the glacial periods. Such a change corresponds to a downward shift of vegetation zones, estimated of 600–1000 m. Simultaneously, glacioeustatic drops in sea level enlarged the surface of the Thai–Malay Peninsula and connected nearly all the islands together. The sea-level drop is estimated to have been at least 100 m (Vorisi, 2000) for the Last Glacial Maximum (LGM) (20 ka), causing the Sunda Shelf to emerge and the Andaman Sea to retreat.

Such a change is supposed to have had a strong impact on the monsoonal climate which led to the development of a savannah corridor in the central flood plain of the Sunda Shelf. The distribution of teak forest (*Tectona grandis*), which widely occurs today in the Northern Province but with isolated patches in Java, supports this hypothesis. Although most authors agree that during the coldest and driest glacial periods, including the LGM, some rainforest refuges existed, they disagree about their location (Kershaw et al., 2001; Gathorne-Hardy et al., 2002; Meijaard, 2003).

Surprisingly, the late Pleistocene period is probably the less well-known period concerning its climate and vegetation, but also concerning its sedimentary deposits, either from caves or from fluvial terraces. In Thailand, among more than 20 investigated fossiliferous caves and fissure fillings, four of them had been assigned to the late Pliocene or the early Pleistocene and all others to the late middle Pleistocene (see Mid-Pleistocene of Southern Asia) (Figures 2 and 3). Only one archaeological site could be assigned to the late Pleistocene (Chaimanee, 1998). Cave filling is the result of a sedimentary process that occurs during phases of heavy rainfall or of tectonic subsidence. At some other periods, erosion is dominant because of the drop of sea level or tectonic uplift. Therefore, the fossiliferous cave sediments document the most recent episode of infilling. In some rare cases, remnants of older filling events can be found as relictual patches left by erosion on the lateral walls of the caves, but they can only be identified if they yield older fossils. Speleothems (calcite deposits) are rarely contemporaneous to the fossiliferous sediments and are usually more recent than fossils. As cave fillings, they are polycyclic and their dating is of little use to date the fossiliferous cave deposits unless they clearly cover the sediments like stalagmitic floors. Terrace deposits are also dependent on climate and tectonic activity (Figures 4 and 5). During periods of low sea levels, river channels cut the former terraces deposits and develop new terraces of minimal width which may be easily eroded during later Holocene flooding. Therefore, the scarcity of late Pleistocene deposits in Southeast Asia can be explained by a peculiar climatic setting. The climate was colder and drier, and these characteristics have been confirmed by the fossil pollen record in Java and Thailand and by the larger than average size of mammals that have extant representatives in the same area. Palynological data are extremely scarce, and most authors refer to the study of Van der Kaars and Dam (1995) in Java where a core documenting the vegetation of the last 135 ka has been investigated. Nevertheless, despite its great interest, it cannot be simply extrapolated to other areas. Recently, however, new data have been provided concerning Thailand, which confirm the extension of a temperate forest during the cooler and drier LGM (Penny et al., 2001; White et al., 2004).

In the light of these considerations, the late Pleistocene mammalian fossil records of Southeast Asia will be reviewed.

Figure 1 Indochinese and Sundaic Province and the Kra Isthmus.

Figure 2 Late Pleistocene and Late middle Pleistocene vertebrate localities in Southeast Asia mentioned in the text.

Late Pleistocene Mammals in Southeast Asia

Sundaic Province

Java

The rich *Homo erectus* record in Java has stimulated much paleontological and biochronological research. However, a fluctuating sea level has caused island isolation and led to

Figure 3 Mammalian community of the middle and late Pleistocene in Thailand.

Figure 4 Cave deposits in limestone are source of Pleistocene fossils in Southeast Asia.

Figure 5 Another important source for Pleistocene mammalian fossils is terrace deposits.

a high endemism, making it difficult to develop a biochronological timescale. Nevertheless, a consensus exists currently that the Kedung Brubus faunal stratum corresponds to a middle Pleistocene faunal assemblage. It is followed by the highly

controversial Ngandong fauna, then by Punung and finally by Wajak, which represents the last faunal assemblage before the extant fauna comes into existence.

The Punung fauna, Wajak fauna, and perhaps also the older Ngandong fauna are considered to be of late Pleistocene age.

Punung faunal assemblage

De Vos (1983) and Sondaar (1984) defined the Punung faunal strata on the first appearance datum (FAD) of the extant Asian elephant (*Elephas maximus*) and the extant pig species (*Sus vittatus*). The Punung Caves fauna has yielded 18 mammalian species including *H. sapiens*. The composite faunal list, from at least two separate caves, I and II, contains no extinct species. The occurrence of orangutans (*Pongo pygmaeus*), siamang (*Hylobates syndactylus*), and sun bear (*Ursus malayanus*), taxa not known to cross water barriers, suggests that a land connection existed at that time with mainland Southeast Asia and that the community lived in a rainforest environment. As orangutans and modern humans are unrecorded from older faunal strata, one can therefore conclude that they are immigrants from the mainland (Van den Bergh et al., 2001). Therefore, this rainforest faunal association probably corresponds to the end of the last interglacial or the beginning of the last glacial.

According to this interpretation, one could also add orangutans and modern humans to the previous list of late Pleistocene FAD on Java. Another interesting point is that if this fauna is really from the terminal part of the last interglacial, it supports the argument that the sea level was, at that time, at least 60–80 m lower than at present day, to permit land mammal exchanges with the Indochinese Province, where some of these taxa (Asian elephant and orangutans) have been documented from older localities. Tham Wiman Nakin Cave in Thailand, for example, which is older than 169 ka, has yielded Asian elephant. It is unfortunate that no absolute ages are available for Punung I and II localities, which have yielded early *H. sapiens*. The presumed age of the Punung fauna is 80–60 ka. Van den Bergh et al (2001) also mention the discovery of Asian elephant from the Cipeundeuy sand pit in Java, located next to Bandung, dated between 35.5 and 29.6 ka by ^{14}C (Van den Bergh, 1999). The site has also yielded a few modern taxa that are still present on that island.

Wajak faunal assemblage

The Wajak fauna is of early Holocene age and has been dated to about $10.56 \pm .075$ ka BP (Storm, 1995). The fauna is modern with 10 large mammal species including *H. sapiens* and four rodent species. *Elephas* is absent and tapir (*Tapirus indicus*) has its last appearance datum (LAD) on the island. According to De Vos (1983) the fauna indicates an open woodland environment and shows that rainforest must therefore have disappeared before 10 ka BP from that area because it lacks the species most strongly adapted to the humid forest.

Ngandong faunal assemblage

The Ngandong faunal composition appears largely similar to the Kedung Brubus fauna. Of the 15 species of large mammals, 9 are extinct and shared with Kedung Brubus (Sondaar, 1984). However, several species, including *H. erectus*, differ at the subspecific level, suggesting a younger age. Van den Bergh et al. (2001) therefore propose an intermediate age of about 135 ka for that faunal assemblage. In contrast, Swisher et al.

(1996) U/Th series dating on Ngandong fossil teeth gave an age between 53 and 27 ka. One dramatic consequence of that absolute age is the putative contemporaneity and sympatry of late *H. erectus* (Ngandong man) with early *H. sapiens*, which has so far never been observed elsewhere in Asia, with the possible exception of Flores Island (Morwood et al., 2004). However, the U/Th series dating method is not accurate in tropical regions where the weathering of dentine and enamel is significant and diagenesis is considerable (Esposito et al., 2002). For these reasons, the attribution of the fauna to the early late Pleistocene by Van den Bergh (1999) is preferred here.

Sumatra

The material collected by Dubois, as early as 1888, originates from three distinct caves: the Lida Ajer Cave near Pajakombo, the Sibrambang Cave, and the Djamboe (Jambu) Cave near Tapisello. The fauna was subsequently studied by Hooijer (1947), who assigned Holocene age to these faunas. However, Drawhorn (1994) used amino acid racemization to date the Lida Ajer Cave fauna from 80 to 60 ka. The Lida Ajer Cave has yielded two teeth of *H. sapiens*, one upper central incisor and one upper left molar associated with 16 other mammalian taxa, including Asian elephant, orangutan, *Hylobates*, all taxa indicative of a rainforest environment. Almost all of these fossil mammal taxa are also present in Sibrambang Cave and have been described by Hooijer in several publications between 1947 and 1962. De Vos (1983) also mentioned additional taxa such as *Rusa* sp., *Muntiacus muntjak*, *S. vittatus*, and *S. barbatus*.

Borneo

The late Pleistocene of Borneo is famous for its historical discovery of the first Southeast Asian modern human skull and associated rich mammalian fauna at Niah Cave (see *Interactions with Hominids*). Several levels have been excavated in recent years and have yielded abundant mammal fossils, from large mammals to rodents (Medway, 1972), including *H. sapiens* (Figure 6). The sequence possibly dated back to more than 40 ka. One white marker bed, which may correspond to ash from the Toba eruption, has been dated to 32.6 ka BP. From the fossiliferous level, 30 extant species of mammals, including six primates (*H. sapiens*, orangutan, *Hylobates*,

Figure 6 Dry screen method was used to separate fossils from cave sediments.

Macaca, *Semnopithecus*, and *Nycticebus*) have been reported with more than eight rodents and insectivores and more than ten species of bats. Asian elephant is also present and, with orangutan, characterizes the Sundaic late Pleistocene faunal assemblage. Only one extinct species, a pangolin, *Manis paleojavanica*, occurs, and the overall assemblage is characteristic of rainforest. Therefore, it demonstrates that this part of Borneo was a rainforest refuge at that time and that *H. sapiens* were already adapted to rainforest environments.

Flores

Island endemic vertebrates have been recorded for many years from Flores (Sondaar et al., 1994; Van den Bergh et al., 1996; Morwood et al., 1998) including dwarf *Stegodon*, giant rat, *Hooijeromys*, and Komodo dragon. However, the recent discovery, in the Liang Bua Cave of a dwarf human skeleton described under the name *H. floresiensis*, interpreted as an island dwarf endemic *H. erectus* and dated to 18 ka, changes the understanding of the faunal evolution of that island. The dwarf *Homo* is associated with an endemic fauna, with a dwarf *Stegodon*, a Komodo dragon, and endemic rats. According to the different absolute dates provided by Morwood et al. (2004), this dwarf human and associated fauna occurs during a time interval spanning 74–37.7 ka up to 18 ka in the cave. This discovery testifies to the long isolation of middle Pleistocene immigrants including *H. erectus*, and furthermore, stone tools as old as 800 ka have been reported (Morwood et al., 1998). Therefore, the FAD of the mainland mammals recorded from Holocene sediments (Van den Bergh et al., 1996) should be younger, from shortly after the LGM, and modern *H. sapiens* may have immigrated simultaneously when the deep-water barrier isolating flores during most of the middle Pleistocene became shallower.

Indochinese Province

The Indochinese Province fauna of the middle and late Pleistocene is characterized by a peculiar mammalian assemblage comprising of *Stegodon orientalis*, *Ailuropoda melanoleuca baconi* (giant panda), and orangutan. The fossil record of these species dates from the early middle Pleistocene, and they survived until the late Pleistocene or even close to the present day. Some even migrated southward to reach the Sundaic Province at an early time and, in the case of *Stegodon*, this probably occurred in several waves. Orangutan and modern human, in contrast, reached Sundaland only during the end of the last interglacial or the beginning of the last glacial, and giant panda never immigrated there. Biochronologically, the Pleistocene period is subdivided by the FAD and LAD of different species. The early Pleistocene is characterized by a primitive species of panda, *Ailuropoda minuta*, *Gigantopithecus*, and several other species which also survived in the earliest middle Pleistocene. This later period (see Mid-Pleistocene of Southern Asia) is characterized by a short-faced hyena (*Hyaena brevirostris sinensis*) which is replaced after migration or extinction by the spotted hyena (*Crocuta crocuta ultima*) whose origin and FAD is problematic. For Kurten (1956), the spotted hyena had reached Southeast Asia between 480 and 450 ka. It also immigrated to Northern China, where it was found in the upper layer of the Choukoutien *H. erectus* locality. Another

biochronological marker is *H. sapiens* whose appearance seems to correspond to the end of the middle Pleistocene. The late Pleistocene fauna of that province can be therefore characterized by the local or total extinction of some mammal species. Giant panda survived in Southern China whereas orangutans survived in Borneo and Sumatra. A similar history has been elaborated for rodents by Chaimanee (1998). Early Pleistocene and early middle Pleistocene rodent faunas contain several genera that became extinct before the late middle Pleistocene, a period that is characterized by the presence of extant species no longer native to Thailand, such as *Hadromys humei*, *Hapalomys delacouri*, *Pithecheir parvus*, *Nannosciurus melanotis*, and *Iomys horsfieldi*. Finally, the late Pleistocene rodent assemblage is characterized by the progressive local extinction of these 'exotic' rodents and by the immigration of some large-sized flying squirrels originating from South China.

Vietnam

Several early to middle Pleistocene mammal faunas are known, but so far only one rich late Pleistocene locality has been reported, the Lang Trang Cave from North Vietnam with 23 species of large- and medium-sized mammals (Vu et al., 1996; Long, 1996). Its age has been estimated between 80 and 60 ka. Primates are represented by *Macaca*, *Semnopithecus*, and orangutan. *S. orientalis* and *Elephas namadicus* are associated with giant panda and tapir, indicating a forest environment of early late Pleistocene age. No human remains have been collected so far from the cave which represents the LAD for *E. namadicus*. The Ma U'O'i Cave in Northern Vietnam (Bacon et al., 2004) has yielded a small fauna with six species of large mammals including *Elephas* and *Homo* sp. and four species of rodents. The age is uncertain since the fauna has a modern composition with no extinct species. The Keo Leng fauna from Northern Vietnam has an 'estimated' age of 30–20 ka (Kha, 1976; Olsen and Ciochon, 1990). It has yielded a rich mammalian fauna of 27 species including *H. sapiens*. Orangutan, giant panda, *Megatapirus augustus*, and *S. orientalis* are indicative of a late middle Pleistocene assemblage, thereby casting doubts on its estimated age. If confirmed, it would indicate that the previously mentioned taxa, with the exception of modern human, survived until the LGM or even later in the Indochinese Province.

Thailand

No precisely dated late Pleistocene mammal fauna has been reported from Thailand, since most Thai caves and fissure fillings have been dated to the late middle Pleistocene (Chaimanee, 1998). Among them, the fossiliferous layer of Tham Wiman Nakin Cave in Northeastern Thailand (see Mid-Pleistocene of Southern Asia) has been dated as older than 169 ka, using speleothems covering the main fossiliferous layer (Esposito et al., 2002). However, uranium–thorium ages obtained from mammalian teeth gave confusing results due to leaching and diagenesis. *Homo*, orangutan, giant panda, and modern Asian elephant therefore existed in Thailand before the last interglacial. Only one fissure-filling locality, the Crystal Cave near Kanchanaburi in Central West Thailand, has yielded a rodent fauna that may be of late Pleistocene age. It consists of only extant species associated with an unusual large species of flying squirrel, which has been interpreted as a large-sized

species, that shifted its range southward during a cold period, as predicted by Bergmann's rule (Chaimanee and Jaeger, 2000a). Many Pleistocene prehistoric excavations, such as Lang Rongrien rockshelter and Moh Kiew Cave in Peninsular Thailand near Krabi, and Spirit Cave and Tham Lod rock shelter near Mae Hong Son in North Thailand, have yielded mammalian remains which have not been published so far. They consist of only modern species. In addition, recent palynological data obtained from three localities in Thailand confirm the hypothesis of a drier and cooler climate during the LGM (White et al., 2004), with a fagaceous–coniferous forest in northeast Thailand (Penny, 2001).

Cambodia

Only one cave fauna in Cambodia, Phnom Loang (Beden et al., 1972) from Kampot Province shows a composition which could correspond with either a late Pleistocene or a late middle Pleistocene age, no absolute dating being presently available. Here, Javan rhinoceros (*Rhinoceros sondaicus*) is associated with spotted hyena. Nearby caves have shown the presence of orangutan, Asian elephant, and tapir. The presence of a spotted hyena supports a late middle Pleistocene age rather than a late Pleistocene one. In that last case, the *C. crocuta ultima* LAD would be latest middle Pleistocene.

Discussion

Several conclusions can be reached from this review. The most important is the lack of absolute dating and the huge imprecision concerning the age of most of these mammalian faunas. The second is that the complex geographic history of Southeast Asia makes it nearly impossible to construct a regional biochronological timescale. Local faunal evolution is strongly related to the main geographical changes induced by sea-level changes and by neotectonic uplift or subsidence. Only in the more stable Indochinese Province, a reliable biochronological scale potentially could be established, but more accurate dating would be necessary.

Late Pleistocene Local and Global Extinctions

Giant panda is today confined to a small range in Southern China at high altitude, with a temperate climate, where it feeds mostly on temperate bamboos. Tougaard et al. (1996) have suggested that climatic cooling and an associated altitudinal drop of vegetation zones caused the extension of the temperate bamboo range on which the giant pandas fed. This would explain their wide Pleistocene expansion. Simultaneously, the same cause could explain the spread of the spotted hyena, which is clearly an open woodlands and grassland species, and its replacement of the short-faced hyena. Both giant panda and spotted hyena never reached the Sundaic Province, probably because of rainforest barriers. Orangutan was also widespread in the Indochinese Province during the middle Pleistocene and migrated later on to the Sundaic Province, where it still survives until today. No data are available concerning the extinction of orangutan in the Indochinese Province, but Bacon et al. (2001) described an orangutan skeleton

from Hao Bin Province (northern Vietnam) that seems to be of very recent age, suggesting a long survival of that species and supporting an anthropic cause for its extinction. Other species have become extinct in both provinces, such as *Megatapirus* in the Indochinese Province and *Duboisia santeng* in the Sundaic Province, before the late Pleistocene. But again, these events are not yet accurately dated and their causes are unknown. A similar situation occurs for the rodents, with the grassland species *Hadromys humei* becoming extinct before the late Pleistocene (Chaimanee and Jaeger, 2000b).

Changing Biogeography and the Fluctuating Boundary between the Indochinese and Sundaic Faunal Provinces

Both of these provinces are characterized by a small number of taxa during most of the late middle and late Pleistocene. Not only extant forms such as *Macaca assamensis*, *Ursus thibetanus*, giant panda, but also extinct ones such as *Crocota*, *S. orientalis*, *E. namadicus*, and *Megatapirus* can be considered as typical markers of the Indochinese Province. The extant gibbon (*Hyllobates syndactylus*) and the pig (*S. barbatus*) for the living species, and *Stegodon trigonocephalus* and *Duboisia santeng* for the extinct taxa, are also characteristic of the Sundaic Province. But many other species were common to both provinces such as *H. sapiens*, tiger, Malayan bear, wild dog (*Cuon alpinus*), tapir, rhinocerotids (*R. sondaicus* and *Dicerorhinus sumatraensis*), wild pig, buffalo, muntjac, Sumatran goat, and several rats, and squirrels. Progress in taxonomic work may increase this list, especially when more small mammals are taken in account. Their association clearly defines a Southeast Asian mammalian assemblage. But the real question concerns the past location of the 'paleo-Kra Isthmus' and its fluctuations. The fossil record yields little information with the exception of a perceptible southward extension of this boundary during glacial periods. The fauna from Tambun locality next to Kuala Lumpur in Malaysia, the age of which is not well established (Hooijer, 1962), contains *E. namadicus*, indicating a southward expanded Indochinese Province fauna. Some extant grassland rodent species, such as *Hadromys humei*, presently restricted to Northeast India and South China, have been found in a late middle Pleistocene locality close to the Thai–Malay border (Chaimanee and Jaeger, 2000b). On the other hand, some Sundaic rats, presently not living in Thailand, such as *Pithecheir parvus*, extended their range northward. Similar examples occurred among squirrels. However, as very few rodents have been described from the Pleistocene localities of Sundaland, it is difficult to follow the complicated history of the fluctuating boundary between these provinces. Nevertheless, many species of rodents showed a larger latitudinal range than today and many ranges did overlap in a much broader ecotone with high small-mammal biodiversity.

Bergmann's Rule and Size Changes

One common feature of Pleistocene fossil mammal communities concerns their composition and the large size of their constituent species. As in other parts of the world at the same time, large herbivores were more numerous than they are at

present. Despite the lack of updated taxonomic studies, six or more large herbivores, two proboscideans and four bovids, have coexisted in these Southeast Asian faunas. Pleistocene herbivores are usually larger than their living representatives. Many factors are involved in controlling adult size of mammals. The most common is Bergmann's rule, which stipulates that warm-blooded animal size increases according to a decreasing mean temperature gradient. This has been demonstrated for the extant *Macaca fascicularis* by Fooden and Albrecht (1993). Hooijer (1949) uses this principle to explain the progressive size decrease of Sundaland mammals, such as orangutans, Javan rhinoceros, tapirs, tigers, and even rodents (Medway, 1972). However, many other factors could have played an important or additional role including interspecific competition and island isolation.

Conclusions

The late Pleistocene mammalian faunas of Southeast Asia are very incompletely known. Many localities have not yet been dated with modern methods and their inferred ages sometimes correspond only to rough estimations. However, some general conclusions can be drawn from the available data. First, the beginning of this period corresponds to the immigration of modern humans in the area. Some scanty human remains attest to the occurrence of *Homo* before 169 ka in Thailand and in several other places in the Indochinese Province, but the fossils are not sufficiently complete to identify these remains to species level. The faunas were distributed into two distinct provinces but their boundary, located today in the Thai Peninsula at the Kra Isthmus, was situated further south during most of the late Pleistocene. Rodent faunas suggest that the transition area, which is sharp today, was much more latitudinally extended. During these periods, savanna was widely expanded and many species were occupying that niche. Probably, many extant forest herbivores were also living in the savanna during the late Pleistocene as indicated by recent unpublished isotopic studies. Sea-level and climatic changes permitted some exchanges between the two provinces, allowing *H. sapiens*, orangutan, and some other species to reach the biotas of the Sundaic Province. Orangutan's present distribution range in Sumatra and Borneo appears also to be a refuge area and not as a center of origin. In the Sundaic Province, many endemic species, including *H. floresiensis*, differentiated through island evolution as a consequence of isolation. It is expected that in future more evidence of island evolution will be discovered. The history of the late Pleistocene fauna consists of the progressive range reduction and the local to total extinction of several species. Two main periods of climatic changes may be responsible for these events. First, the Late Glacial Maximum, some 20 ka, corresponded to an important cooling and extension of savanna. It was followed, about 10 ka, by the Holocene warming which was associated with a dramatic expansion of the rainforest that led to the present biogeographic situation. The causes of the local extinctions, as those of the spotted hyena, *Stegodon*, giant panda, and orangutan in the Indochinese Province, are not well understood, since the importance of the human factor cannot yet be evaluated (see Late Pleistocene Megafaunal Extinctions). Finally, the modern

distribution of mammals has developed only very recently, after a long period of relative stability during the middle and late Pleistocene.

Late Pleistocene Megafaunal Extinctions

S A Elias and D C Schreve, Royal Holloway, University of London, Egham, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

From the late nineteenth century, the work of paleontologists was beginning to reveal the fact that many of the large animals that had lived during what was then known as ‘The Great Ice Age’ are no longer living today. The great evolutionary biologist, Alfred Russel Wallace, wrote the following memorable comment on this phenomenon in 1876:

We live in a zoologically impoverished world, from which all the hugest, and fiercest, and strangest forms have recently disappeared; and it is, no doubt, a much better world for us now they have gone. Yet it is surely a marvellous fact, and one that has hardly been sufficiently dwelt upon, this sudden dying out of so many large mammalia, not in one place only but over half the land surface of the globe. (1876, p. 150)

Thirty years later, speculating on the causes of this extinction event, Wallace ventured the following:

Looking at the whole subject again, with the much larger body of facts at our command, I am convinced that the rapidity of . . . the extinction of so many large Mammalia is actually due to man’s agency, acting in co-operation with those general causes which at the culmination of each geological era has led to the extinction of the larger, the most specialised, or the most strangely modified forms. (1911, p. 264)

Thus the comments of Wallace set the stage for a modern discussion of this phenomenon. Today we know a great deal more about the timing of these extinctions, the number of species involved, and the geographic patterns of extinction, but much of the mystery remains, and the debate over the cause(s) of the late Pleistocene megafaunal extinction continues to rage on in the current literature.

Definition of Megafauna

The fossil evidence from many continents points to the extinction mainly of large animals at or near the end of the last glaciation. These animals have been termed ‘megafauna.’ The most common definition of megafauna is an animal with an adult body weight in excess of 44 kg (Martin, 1984). These animals were worst affected because they exist at relatively low density in the landscape, mature late, and have few offspring. They are slow to recover numbers after any collapse of population. In many regions of the world, the Pleistocene megafauna was dominated by herbivorous mammals, such as the woolly mammoth and woolly rhinoceros. However, in biologically isolated regions of the world, such as Australia and New Zealand, the Pleistocene megafauna also included other vertebrate groups, such as large flightless birds, and giant turtles and lizards. One of the most curious aspects of late Pleistocene megafaunal extinctions is that they affected some continents far more than others (Table 1). For reasons

which are still being debated, Australia and the Americas were much harder hit than Africa and Asia. In the next section, we discuss the extinction patterns of the various continents.

Extinctions Before the End of the Last Glaciation

The extinction of late Pleistocene megafaunal species was not a singular event, but rather a process that spanned many thousands of years. It was also time-transgressive on the various continents, so it was not tied to a single global climatic change, and even within individual species, with key taxa being lost from certain areas before others. One of the difficulties in developing an understanding of megafaunal extinction is that it is very difficult to pin down an exact time when a given species ceased to exist, just by examining the fossil record. When the fossil bones of a given species fail to appear above a certain stratigraphic horizon in a region, we assume that this species had died out, at least in that region. However, as the old proverb says, “Absence of evidence is not evidence of absence.” The discovery of any younger fossils will, of course, mean that the extinction date has to be revised. One of the most startling examples of this concerns the woolly mammoth, probably the best known Pleistocene megafaunal mammal, based on its appearance on the logos of Quaternary research organizations. Until quite recently, paleontologists believed that the woolly mammoth became extinct at the end of the last glaciation, perhaps 12 800 years ago (Elias, 1999). Then a Russian paleontologist discovered woolly mammoth bones from Wrangel Island, off the northeast coast of Kamchatka. These bones were radiocarbon dated, and found to be only 4079 years old (Long et al., 1994). Thus the date of extinction for this species had to be revised by 8700 years, placing its last appearance well within the Holocene. Since then, other species have similarly been found to survive into the current interglacial (Stuart and Lister, 2007).

The Wrangel Island woolly mammoth story is a cautionary tale, and it also highlights a different aspect of the demise of the megafauna: extinction versus extirpation. Extirpation is the dying out of a species in a given region. For instance, the fossil evidence indicates that woolly mammoths were extirpated from mainland North America by 12 800 years ago. Extinction refers to the worldwide demise of a species. There is a very important difference between these two phenomena, because, during the Pleistocene, extreme environmental changes caused the regional extirpation of countless numbers of species in the middle and high latitudes, time and again. However, as long as populations of a given species were able to survive in other regions (perhaps only a single population in one region), then that species had a chance to survive until environmental conditions in its former range became more favorable again. The fossil record of the Pleistocene is replete with examples of the regional waxing and waning of plant and animal

Table 1 Megafaunal extinctions (genera) during the last 100 ka

Continent	Extinct	Living	Total	Extinct (%)	Landmass (km ²)
Africa	7	42	49	14.3	30.2 × 10 ⁶
Europe	15	9	24	60.0	10.4 × 10 ⁶
North America	33	12	45	73.3	23.7 × 10 ⁶
South America	46	12	58	79.6	17.8 × 10 ⁶

populations, in the face of climate change and glaciation. Extinction, however, is permanent. When a species' unique genotype is lost to the world, it cannot come back. In the next section, we examine the regional history of the timing of megafaunal extinctions (keeping in mind the caveats discussed above about evidence of absence).

Australia

The continent of Australia has been geographically isolated from much of the rest of the world for many millions of years. The only groups of mammals to successfully colonize Australia were the primitive group of marsupials. In marsupial mammals, the female typically has a pouch (marsupium) in which it rears its young through early infancy, thereby differing from placental mammals, which give birth to fully formed young. Placental mammals have dominated the mammalian faunas of the other continents since the Late Tertiary, but the marsupials were the only mammal group in Australia. In the absence of competition from placental mammals, the Australian marsupials radiated to form a rich and diverse Pleistocene megafauna, including giant herbivores, such as *Procoptodon*, a giant kangaroo (Figure 1(c)), and *Diprotodon*, a lumbering rhinoceros-sized marsupial (Figure 1(a)). The megafaunal group that suffered the greatest number of extinctions in the late Pleistocene was the short-faced kangaroos in the subfamily Sthenurinae. Approximately 14 species of sthenurines died out in the late Pleistocene; only one species survives today. The hind feet of these kangaroos had a single toe, with a broad, flattened claw that resembled (and may have acted as) a horse's hoof, reflecting an adaptation to rapid movement through progressively open, arid grasslands.

Giant wombats and wallabies also roamed the grasslands of Pleistocene Australia. One of the most unusual of these was the giant wombat, *Phascolonus gigas* (Figure 1(b)), that weighed up to 200 kg, and was built for burrowing. Flannery (1994) speculated that it was the giant dirt piles adjacent to these burrows that alerted human hunters to the presence of these animals, ultimately leading to their demise.

In the place of placental mammal predatory groups such as wolves, large cats, and bears, the marsupial predators of Australia included *Thylacoleo*, the equivalent of a Pleistocene lion (Figure 1(d)), and *Sarcophilus*, an ancestral Tasmanian devil. Based on its skull and teeth, *Thylacoleo* appears to have been a ferocious predator with arboreal adaptations. It had an enormous set of stabbing front teeth, slicing carnassials, and

Figure 1 Australian megafaunal species that became extinct in the late Pleistocene. (a) *Diprotodon optatum*, from Long et al. (2002, p. 87). (b) *Phascolonus gigas*, from Long et al. (2002, p. 113); (c) *Procoptodon goliah*, from Long et al. (2002, p. 158); (d) *Thylacoleo carnifex*, from Long et al. (2002, p. 105); (e) *Zygomaturus trilobus*, from Long et al. (2002, p. 99); (f) *Megalania* chasing *Genyornis*, from University of California Berkeley Website: <http://www.geology.ucdavis.edu/cowen/HistoryofLife/CH18images.html>.

powerful claws. Paleontologists have equated it with the modern leopard, killing its prey, and then dragging the carcass up a tree to feed (Long et al., 2002). *Sarcophilus*, the modern Tasmanian devil, had a Pleistocene relative that was about 16% larger than the modern species. It was not technically part of the megafauna, weighing only 10 kg, but as with the modern species, the Pleistocene variety probably 'fought above its weight.'

Other groups of vertebrates flourished in the absence of placental mammals in Australia. These included a large flightless bird, *Genyornis* (Figure 1(f)), crocodiles, the giant madtsoiid snake *Wonambi naracoortensis*, giant horned turtles, and the giant predatory 'ripper lizard,' *Megalania prisca* (Figure 1(f)), a relative of the modern monitor lizard or goanna and the largest terrestrial lizard known. The Australian Pleistocene bestiary could well fit Wallace's description of 'large, fierce, and strange.' Then, beginning about 50 000 years ago, they started dying off (Table 2).

There are a number of important fossil sites in Australia that have yielded abundant, well-preserved megafaunal remains. Perhaps the best known of these is the caves contained in the Naracoorte Caves National Park, South Australia. These are

limestone solution caves that formed in the early Pleistocene and which acted as giant pit-fall traps in the last 500 000 years. To date, 118 species of vertebrate animals have been recorded representing four of the major vertebrate groups: the amphibians, reptiles, birds, and mammals. Many of these qualify as megafauna, based on their estimated size. Mammoth Cave, another limestone cave, lies near the southwest tip of Australia in New South Wales. More than 10 000 late Pleistocene bones have been found in the cave, some greater than 35 000 years old. The fossils include the remains of a Tasmanian devil, the 'marsupial lion' (*Thylacoleo*), the giant echidna (*Zaglossus hacketti*), and a Pleistocene short-faced kangaroo (*Simosthenurus*). Pleistocene fossil localities are dotted across much of southern and eastern Australia (Figure 2). While the cave sites, such as the ones described above, have yielded spectacular bone piles, there are hundreds of open-air sites as well. For more complete inventories of sites, see Horton (1989) and Roberts et al. (2001).

The Australian megafauna contained many large animals (Figure 3), but few that were true giants, compared with the many megafaunal species in Eurasia and the Americas that weighed several tons. Flannery (1994) attributes the paucity of extremely large megafaunal species in Australia to the low level of nutrients available in Australian soils. Also, because of

Australia's geographic isolation since before the evolution of placental mammals on other continents, vertebrate groups other than mammals, such as flightless birds and reptiles, played a larger role in Australian Pleistocene faunas than they did elsewhere. Notable among these were giant snakes, lizards, and crocodiles (although for an opposing view, see Wroe, 2002).

The story of Australian megafaunal extinction is confounded by a relatively poor chronology, and new information is being obtained with great frequency, but the main pulse of extinction came here much earlier than elsewhere in the world. Roberts et al. (2001) dated the youngest sedimentary layers containing megafaunal species, using a variety of methods, including optically stimulated luminescence (OSL) and U/Th. They placed the extinctions all within a window from 51 200 to 39 800 (95% confidence interval), substantially earlier than the main waves of extinction on other continents. Barnowsky et al. (2004) cite the following statistics: of 21 extinct genera of Australian megafauna, 12 persisted to at least 80 000 years ago, and at least 6 persisted to between 51 000 and 40 000 years ago. Wroe et al. (2004) produced a slightly different reckoning of these events, with 19 genera becoming extinct in the Pleistocene, rather than 21. The differences are mostly due to different taxonomic classification schemes, but the bottom

(2001). 1, Ned's Gully; 2, Mooki River; 3, Cox's Creek (Bando); 4, Cox's Creek (Kenloi); 5, Tamar Springs; 6, Cuddie Springs; 7, Lake Menidee (Sunset Strip); 8, Willow Point; 9, Lake Victoria (Site 50); 10, Lake Victoria (Site 51); 11, Lake Victoria (Site 73); 12, Montford's Beach; 13, Lake Weering; 14, Lake Corangamite; 15, Lake Weeranganuk; 16, Lake Colongulac; 17, Warrnambool; 18, Victoria Fossil Cave (Grant Hall); 19, Victoria Fossil Cave (Fossil Chamber); 20, Wood Point; 21, Lake Callabonna; 22, Devil's Lair; 23, Kudjal Yolgah Cave; 24, Mammoth Cave; 25, Moondyne Cave; 26, Tight Entrance Cave; 27, Du Boulay Cave.

line remains the same: roughly 86% of the Australian megafauna died out before 16 000 years ago, leaving only three genera of large mammals in the Holocene. In one of the best constrained chronologies of megafaunal remains from Tight Entrance Cave in southwestern Australia, Ayliffe et al. (2008) dated the last appearance of the short-faced kangaroo, *Simosthenurus*, between 50 000 and 48 000 years BP. However, not all fossil faunas are so well dated, making the timing of Australian megafaunal extinctions, and possible associations with human hunting, a matter of some controversy. The interpretation of the fossil record at the Cuddie Springs site (Figure 2, No. 6) is a good example of this.

Cuddie Springs is an ancient lake bed in the semiarid zone of northcentral New South Wales. Pleistocene megafaunal remains have been found there in a clay pan in the center of the lake bed. The fossil bones were discovered in the 1870s when a well was sunk in the center of the ancient lake bed. Paleontological research began there in earnest in the 1930s, and five megafaunal species have been identified from the site. The work there eventually led to the discovery of stone tools and evidence of butchering of animals (cut marks on fossil bones). The most significant archaeological discovery was made in one of the lower levels at the Cuddie Springs site. A small flaked stone tool (possibly an arrowhead or scraper) was found lodged between a *Diprotodon* mandible and a *Genyornis* femur. The tool had traces of dried blood, and the wear patterns were consistent with its use in butchering. But when did these events take place?

Figure 3 Silhouettes of most of the extinct late Pleistocene Australian vertebrate species drawn to scale (human hunter provides scale). Row 1, right to left: Tree-feller (*Palorchestes azael*), marsupial 'rhino' (*Zygomaturus trilobus*), large and small diprotodons (*Diprotodon optatum*, *D. minor*), Euowenia (*Euowenia grata*). Row 2, Marsupial lion (*Thylacoleo carnifex*), five species of extinct wombats (*Ramsayia curvirostris*, *Phascolonus gigas*, *Phascolomys major*, *P. medius*, *Vombatus hacketti*, *Phascolarctos stirtoni*), giant rat-kangaroo (*Propleopus oscillans*). Row 3, Seven species of giant short-faced kangaroos (*Procoptodon goliath*, *P. rapha*, *P. pusio*, *Sthenurus maddocki*, *S. brownei*, *S. occidentalis*, *S. orientalis*). Row 4, Eight species of extinct kangaroos (*S. gilli*, *S. atlas*, *S. tindalei*, *S. pales*, *S. oreas*, *S. andersoni*, *Troposodon minor*, *Wallabia indra*). Row 5, Seven species of extinct or dwarfed kangaroos (*Protemnodon roechus*, *P. anak*, *P. brehus*, *Macropus ferragus*, *M. (Osphranter) birdselli*, *M. siva*, *M. titan*). Row 6, Extinct or dwarfed marsupials and monotremes (*M. tama*, *M. thor*, *M. piltonensis*, *M. goodi*, *M. stirtoni*, *Sarcophilus laniarius*, *Zaglossus hacketti*, *Z. ramsayi*). Row 7, Extinct birds and reptiles (*Progura naracoortensis*, *P. gallinacea*, *Genyornis newtoni*, *Megalania prisca*, *Wonambi naracoortensis*).

Radiocarbon dating of butchered remains indicates that this activity took place between about 40 000 and 31 000 years ago. However, there are numerous problems to be considered when radiocarbon dating of collagen extracted from bones that have been repeatedly wetted and dried in a hot climate, so these ages are suspect. Roberts et al. (2001) subsequently obtained OSL dates between 30 and 27 ka on sand grains from the megafaunal fossil beds, but they dismiss the apparent age of the site on the grounds that sediment mixing has occurred there and that the remains must have been reworked. Field and Fullager (2001), who have worked at the site, refute this interpretation. In their view, the megafauna disappeared from the Cuddie Springs record around 28 000 years ago, well after the arrival of humans in Australia. The view of the archaeologists who have studied Cuddie Springs is that after the lake dried out, people lived on and around the clay pan, broadening their resource base to include a range of plant foods. Megafauna appear to be just one of a range of food resources exploited during this time. The archaeological evidence suggests no specialized strategies for hunting megafauna. Thus, depending on which interpretation of the Australian fossil record one

chooses to believe, the megafauna either died out very shortly after the arrival of humans, about 50 000 years ago, or it persisted for tens of thousands of years afterwards. However, more recent dating work on this site done by Grün et al. (2010) casts doubt on the dating of the site. Grün and his colleagues analyzed more than 60 fossil bones and teeth from Cuddie Springs by laser ablation inductively coupled plasma mass spectrometry. They also analyzed 29 fossil teeth using electron spin resonance. They concluded that either the sediment layers that yielded the bones at Cuddie Springs are significantly older than the previous OSL estimate of 30–27 ka, or that a large fraction of the faunal remains and charcoal from this layer are reworked from older deposits that came from the sides of the spring.

The Americas

The ancient megafauna of the Americas were very different from that of Australia, but this is not to say that the Americas were not home to some very strange beasts during the Pleistocene. Many forms of Pleistocene mammals remain familiar to us today, even if they are no longer native to the New World. The predators include lions and cheetahs, bears, and wolves, albeit larger sized versions than exist today. Many of the Pleistocene herbivores also have modern counterparts, such as camels, horses, bison and muskoxen, deer, and elephants. Again, their Pleistocene counterparts were generally larger than the Holocene survivors. These include a host of different giant armadillo-like creatures known as Glyptodonts (Figure 4(g)). These were particularly important in the Pleistocene fauna of South America. South America was geographically isolated from the rest of the world during the heyday of mammalian evolution in the Tertiary (65–3 million years ago). With the formation of the Isthmus of Panama, about 3 million years ago, a land connection finally allowed the interchange of mammalian faunas from North and South America. Some large herbivores, such as the mastodon (Figure 4(i)) and some related proboscideans, deer, and bears, were able to colonize South America, but the large variety of ground sloths persisted through this interval, and some species of ground sloths and armadillos spread into North America. Some of the ground sloths were true giants. For instance, *Megatherium* was about 6 m long and weighed 4000 kg.

Of the North American megafauna that existed at the beginning of the last glaciation, only three genera are known to have become extinct before 16 000 years ago. The timing of the extinction of 12 genera remains relatively uncertain (Barnowsky et al., 2004), but the remaining extinctions (20 genera) apparently took place between 16 000 and 11 500 years ago (Table 3).

The South American extinction data are much more vague, because less work has been done here. Of the 48 genera of megafauna that have become extinct in the last 100 000 years, we have more-or-less certain evidence that 17 died out between 16 000 and 11 500 years ago (Table 4). Twenty-seven genera died out sometime in the last 100 000 years, but the timing of their extinction remains uncertain (Barnowsky et al., 2004). Four megafaunal genera are known to have persisted into the early Holocene, and then died out. All told, the North American megafauna suffered a 73% reduction in genera by the end of the Pleistocene, and the South America megafauna suffered almost an 80% reduction in genera. Recent careful assessment of

Figure 4 American Megafauna that became extinct in the late Pleistocene. (a) *Arctodus simus*, from Lange (2002, p. 101); (b) *Chasmaporthetes ossifragus*, from Lange (2002, p. 113); (c) *Cervalces scotti*, from Lange (2002, p. 140); (d) *Eremotherium rusconii*, from Lange (2002, p. 84); (e) *Nothrotheriops shastensis*, from Lange (2002, p. 91); (f) *Doedicurus*, from Lange (2002, p. 72); (g) *Glyptotherium arizonensis*, from Lange (2002, p. 72); (h) *Mammuthus columbi*, from Lange (2002, p. 167); (i) *Mammuth americanum*, from Lange (2002, p. 167).

radiocarbon dates on megafaunal remains by Barnosky and Lindsey (2010) indicates that most species persisted until after humans arrived in South America. Most species persisted a thousand years or more after human arrival, and some apparently survived more than 6000 years after this. The geographic pattern of last appearance is variable, but shows the strongest correlation with the arrival of humans in southern and eastern South America, between about 13 500 and 11 200 years ago. This was also a time of rapid environmental change, and the authors conclude that the combination of hunting pressure and environmental change drove most of the South American megafauna to extinction.

Regions Suffering Few Late Pleistocene Megafaunal Extinctions

In contrast, some regions of the world saw few megafaunal extinctions during the late Pleistocene. Some of these regions, such as Africa and southern Asia, preserve the only living examples of the types of animals that died out elsewhere,

such as lions, hyenas, elephants, native horses, and rhinoceroses. Their survival in these parts of the globe begs the question of the cause of their extinction elsewhere.

Africa

Of all the continents, Africa was the least affected by the late Pleistocene megafaunal extinction. The modern African fauna includes 42 genera of large mammals; only seven genera died out during the last 100 000 years, according to Wroe et al. (2004). Barnowsky et al. (2004) listed four genera that became extinct in Africa sometime during the last 100 000 years (Table 5). These include a genus of Pleistocene elephants (*Elephas*) of which the only surviving species is the Asian

elephant (*Elephas maximus*), a genus of Pleistocene three-toed horses, a Pleistocene camel, and a Pleistocene bison. Since about 11 500 years ago, the hartebeest, a genus of African buffalo (*Parmularius*), and the genus of modern cattle (*Bos*) became extinct in Africa. Thus the African megafauna suffered the loss of only about 14% of their genera in the last 100 000 years – the smallest faunal decline of any continent.

Eurasia

Eurasia, like Africa, suffered relatively few megafaunal extinctions in the late Pleistocene (Table 6). Of the ten genera that died out, one became extinct sometime between 100 000 and 50 000 years ago (the straight-tusked elephant, *Palaeoloxodon*

[*Elephas antiquus*], one was extirpated from Europe (the hippopotamus), and three more became extinct between 50 000 and 16 000 years ago (the interglacial rhinoceros, *Stephanorhinus*; a cave bear, *Ursus spelaeus*; and a heavy-bodied Asian antelope, *Spirocerus*) (Barnowsky et al., 2004). The spotted hyena apparently died out in Asia by about 32 000 years ago, roughly corresponding to the onset of the last glaciation (Stuart and Lister, 2007). Another predator, the cave lion (*Panthera spelaea*), became extinct in Eurasia between 14 500 and 14 000 years ago, as climates warmed and shrubs and trees expanded their ranges at the expense of the open steppe-tundra habitat preferred by this species (Stuart and Lister, 2011). Woolly rhinoceros (Figure 5(b)) was extirpated from Western Europe and probably the rest of Eurasia by 16 000–14 000 years ago (Stuart and Lister, 2007). The woolly mammoth (Figure 5(a)) died out in Eurasia by the early Holocene (~11 000 years ago), except for the Wrangel Island mammoth population discussed above. Finally, giant deer (*Megaloceros*; Figure 5(c)) became extinct in much of Eurasia about 11 500 years ago, but a recent dating project has uncovered the fact that giant deer populations persisted in Western Siberia and the Ural Mountains until about 7800 years ago (Stuart and Lister, 2007). Such revisions for the age of extinction will undoubtedly continue to push extinction dates into younger time horizons in the coming years.

Late Pleistocene archaeological sites at Mezin, Mezhirich, and elsewhere in the Ukraine were originally held up as evidence of large-scale hunting of woolly mammoths, because the huts built by Paleolithic hunters were made almost exclusively of carefully piled mammoth bones. For instance, the Mezhirich site contains the stacked bones of at least 149 individual mammoths. The bones subsequently yielded radiocarbon ages ranging from 22 000 to 14 000 ¹⁴C years BP (Lister and Bahn, 1994). Upon closer inspection, they were found to be in

Figure 5 European megafaunal species that became extinct in the late Pleistocene or Holocene. (a) *Mammuthus primigenius*, from Lange (2002, p. 176); (b) *Coelodonta antiquatus*, from Lange (2002, p. 136); (c) *Megaloceros giganteus*, from Poortvliet (1994, p. 173).

various states of preservation, and many had been gnawed by carnivores. It now appears that the humans who made shelters from mammoth bones had not killed the mammoths in large-scale attacks, but had rather collected most, if not all, of the bones of dead mammoths from the treeless landscape for use as building materials. The bone huts thus bear testimony to a huge thriving mammoth population in this region during the last Pleistocene.

Theories on the Causes of Late Pleistocene Extinction

To return to a question posed earlier, why should some regions of the world have been relatively immune from megafaunal extinctions while others suffered losses of up to 80% of their large animal genera? What can we glean from the geographic patterns discussed above? Finally, what role, if any, did human beings play in the demise of these large animals? The last question has driven the study of late Pleistocene megafaunal extinctions in the last 40 years. Researchers who have worked on this topic seem to be divided into two main camps: those who believe that humans played a significant role in these extinctions, and those who lay the blame on natural environmental change. As we shall see, the debate has become quite heated at times, with some of the environmental-change champions (perhaps prematurely?) declaring victory over their opponents in the human-induced extinction camp.

Martin's Pleistocene Overkill Hypothesis

The paleontologist, [Paul Martin \(1967\)](#), wrote a highly influential chapter entitled 'Prehistoric Overkill' for a book entitled *Pleistocene Extinctions, the Search for the Cause*. In this publication, and in his subsequent (1984) book chapter, he propounded the theory that humans were the chief cause of late Pleistocene megafaunal extinctions. Martin's theory rested on several tenets that have since been attacked by other authors. He argued that: (1) the large Pleistocene mammals were decimated by in these extinctions; (2) small mammals (except on islands) were relatively untouched by extinction during the late Pleistocene; (3) large mammals survived best in Africa; (4) the extinctions were often quite sudden; (5) the extinctions took place at different times on different continents; (6) the extinctions occurred without replacement by new taxa; (7) the extinctions followed in man's footsteps; and (8) the archaeology of extinction is obscure. Martin argued that large mammals were the preferred prey of Paleolithic hunters who specialized in big game hunting. Species living on continents not previously inhabited by people would have had little or no fear of humans, making them easier to kill. For the continents of North and South America and Australia, newly colonized by humans during the last Ice Age, Martin envisioned waves of human hunters, fanning out across new lands, killing the large mammals in a 'blitzkrieg,' thus bringing on megafaunal extinction. Such decimation failed to occur in Eurasia and Africa precisely because humans had been hunting on these continents for hundreds of thousands of years. Hence the megafauna of Eurasia and Africa, wary of human predation, were not as easily killed.

Few subsequent authors have really argued with Martin's points 1, 2, 3, 5, 6, and 8. The chief arguments have been over points 4 and 7, which are the most controversial because the evidence concerning them is so difficult to pin down. Let us deal with points 4 and 7 as best we can, in light of recent investigations.

The Environmental-Change Hypothesis

What is clear from the fossil record is that megafaunal extinctions occur equally in areas where there are few or indeed no people, thereby casting doubt on the requirement for human intervention in the process. The suddenness of the extinction events has been called into question by a number of authors. Grayson (1987) began his attack on the megafaunal overkill theory shortly after Martin's major work on the subject was published. Arguing from the North American data, he suggested that numbers of individuals of megafaunal species may already have dwindled before 14 000 years ago, and that many of the genera that have yet to be dated to terminal Wisconsin (last glacial) times may not have survived beyond 14 000 years ago. In the almost 20 years since this article was written, a considerable number of new radiocarbon ages have been established for last-known examples of many North American megafaunal species. By the late 1990s, a suite of 140 AMS ^{14}C dates had been done on proteins extracted from fossil bones of North American megafaunal mammals that died near the end of the last glaciation. The results of that study were quite startling ([Elias, 1999](#)). It appears that the major megafaunal extinction event took place at 13 300 years ago (11 400 ^{14}C years BP). This event included the extinction of camels, horses, giant sloths, Pleistocene bison, and all other genera of megafaunal mammals that did not survive into the Pleistocene, with the exception of the proboscideans. Mammoths and mastodons persisted until about 12 850–12 830 years ago (10 900–10 850 ^{14}C years BP). So it now appears that there were two distinct extinction episodes in North America, with each event taking less than 100 years.

The older event may have taken place before, during, or just after the first appearance of Clovis artifacts in the archaeological record. The Clovis culture is the first widely accepted human occupation in the ice-free regions of North America. The most recent evaluation of the age of Clovis sites in North America ([Taylor et al., 1996](#)) places the beginning of this culture about 13 500 years ago (11 500 ^{14}C years BP). If the people who used Clovis tools arrived in North America at that time, then they overlapped only very briefly with many megafaunal mammal species. Is there a cause and effect or merely a coincidence here? There is good (although sparse) evidence that Clovis hunters killed and butchered mammoth and mastodon, the megafaunal species that died out a few centuries later. Whether human predation was entirely responsible for the proboscidean extinction remains an open question.

In their review of the topic, Grayson and Meltzer (2003) argue that Martin's overkill model does not work for North America, because there is virtually no evidence that supports it, and there is a large body of evidence that argues against it. The lack of archaeological evidence for overkill is something that Martin himself predicted in point 8 of his overkill theory. He argued that the extinction event took place so rapidly that it

would have left little or no trace on the landscape. Paleoindians were apparently nomadic people, and their wanderings left few permanent marks on the landscape in any case. It is difficult, at best, to argue from negative evidence, and Grayson and Meltzer (2003) castigate Martin for so doing, but Fiedel and Haynes (2003), in their response to Grayson and Meltzer's article, point out that large animal bones have rarely if ever been found in any North American archaeological sites, spanning the past 12 500 radiocarbon years. Therefore if no Holocene 'big game hunting' sites can be found, one cannot expect the Pleistocene to be any better represented.

Proponents of environmental change as the instrument of megafaunal extinction in North America often point to the large-scale changes in plant communities that occurred during the Pleistocene–Holocene transition. These changes, mostly noted in fossil pollen records, yielded plant communities for which there are no modern analogs. However, Gill et al. (2009) studied a suite of Late Glacial-age sites in the eastern and central United States, and concluded that it was the loss of megafaunal herbivores that altered plant community structure, not the other way around. They argue that the decline in megafaunal populations released palatable hardwood species from herbivore pressure, bringing about substantial changes in regional plant communities.

Another open-ended question that affects this debate concerns the time of arrival of humans in the Americas. The traditional 'Clovis-First' view that was prevalent when Martin formulated his overkill theory. In the past 20 years, a number of candidate archaeological sites have come to light that indicate a pre-Clovis occupation of the Americas, the strongest of which is the Monte Verde site in Chile (Dillehay, 1997). Evidence from this site unequivocally places people in South America by 15 000 cal years BP. Bona fide pre-Clovis sites have been more difficult to document in North America. Sites such as Meadowcroft, Pennsylvania (Adovasio and Carlisle, 1984), Cactus Hill, Virginia, and Mud Lake, Wisconsin (Falk, 2004), offer tantalizing, if controversial, evidence that people may have been in North America 15 000–20 000 years ago. If these claims can be substantiated, then Martin's theory would be considerably weakened, as one of its principal tenets ('extinction followed in man's footsteps') would be invalidated.

Scott (2010) raised the issue that late Pleistocene megafaunal extinctions in North America may have been driven by competitive pressure from the genus *Bison*, recently arrived from Eurasia across the Bering Land Bridge. In his view, the spread of *Bison antiquus* on the grasslands south of the Laurentide and Cordilleran ice sheets during the last glaciation constituted a major change in regional ecosystems. This species and *Bison bison* formed very large herds and enjoyed competitive advantages over other megafaunal grazers (Guthrie, 1980). Scott proposed that this competitive advantage, in combination with environmental changes at the end of the last glaciation, was the dominant force in driving other the megafauna to extinction in North America. Previous authors had argued that bison had only risen in numbers after the other megafauna became extinct, but radiocarbon dated remains of bison and the other megafauna (Figure 6) show that bison were already increasing in abundance before the demise of the other megafauna.

Figure 6 Bar graphs depicting the number of radiocarbon-dated samples of *Bison* and all other megafaunal species in thousand-year increments, during the last 30 000 years in North America. Data from McDonald (1981) and Guthrie (2006).

Meanwhile, in Australia, the debate about Pleistocene overkill likewise rages on. Miller et al. (1999) discussed evidence for the extinction of the large flightless bird, *Genyornis*, dating this extinction to 50 000 years ago, based on ages from fossil eggshells. They argued that people had arrived in Australia by this time, and that humans were either directly responsible for the demise of *Genyornis* and other Australian megafauna, or indirectly responsible. The latter argument asserts that the early human inhabitants of Australia set fire to large tracts of grassland, in order to boost grassland productivity at the expense of trees and shrubs, and that this caused the collapse of long-established elements of the ecosystem, including the demise of browsers that relied on tree and shrub vegetation for food. In the Miller et al. (1999) argument, the demise of megafaunal predators followed the extinction of their large herbivore prey. Roberts et al. (2001) also discussed evidence from 27 sites that a continent-wide extinction event took place in Australia, about 46 000 years ago. Turney et al. (2008) added more evidence for human-induced megafaunal extinction in Australia. They presented refined age estimates for the timing of megafaunal extinction on the island of Tasmania, which was connected to the mainland during intervals of low sea level. They showed that some megafaunal species survived on Tasmania until at least 41 000 years BP – after the time of their extinction on the mainland but coinciding with the timing of the arrival of humans. They also presented evidence showing that no significant environmental changes took place in Tasmania between 43 000 and 37 000 years ago, when a land bridge connected the island to the mainland. They concluded that human hunting pressure drove the Tasmanian megafauna to extinction.

However, the environmental-change camp also has its champions in Australia. Wroe et al. (2004) argued that no megafaunal kill sites have been found in Australia, and that it is probable that early human populations were too small to bring about rapid extinctions of large mammals. They also argued that more recent evidence from the Cuddie Springs site indicates that *Genyornis* did not die out there until 40 000 years ago. Johnson (2005) takes the middle ground between the two extreme views when he argues that, despite evidence for younger ages of extinctions in various parts of Australia, “the evidence supports overkill, not climate change, as the cause of the extinctions.” For obvious reasons, he rejects the ‘blitzkrieg’ model of extinction, but supports humans as the cause, albeit on a slower time scale.

The Hyperdisease Theory

An alternative theory for megafaunal extinction has been proposed by MacPhee and Marx (1997). In their theory, a particularly virulent strain of an unknown, deadly disease was able to make the jump from one mammal species to another, becoming a hyperdisease that wiped out the megafauna. In the hyperdisease theory, humans may have carried the source of infection from one continent to another as they spread across the world. If the pathogen was able to infect immunologically vulnerable populations of mammals, it would have caused rapid population crashes, possibly leading to extinction. Humans were not necessarily the vectors of such a disease. The carriers could have varied from place to place, following in the footsteps of human colonization. MacPhee and Marx include rats or fleas, or parasites of rats and fleas, on their list of potential disease vectors. As of this writing, no firm evidence has been found to support this theory.

The Bolide Impact Theory

Another theory of late Pleistocene megafaunal extinction was published by Firestone et al. (2007). These authors suggested that the cause of this extinction, plus the cause of the demise of the Clovis culture in North America, was a meteoric fireball, or bolide, that detonated over North America at the onset of the Younger Dryas interval. According to this theory, the exploding bolide kindled wildfires across the continent, leading to a catastrophic reduction in the food plants needed by megafaunal herbivores. The authors claim to have found micrometeorite fragments imbedded in fossil megafaunal mammal bones from this interval, and that sediments from a broad region of North America have been found to contain magnetic grains with iridium, magnetic microspherules, charcoal, soot, carbon spherules, and nanodiamonds (Kennett et al., 2009). This phenomenon is supposed to have triggered the Younger Dryas cooling throughout the Northern Hemisphere, as the meteor struck the Laurentide ice sheet, causing catastrophic melting, sending large volumes of cold fresh water into the North Atlantic, and thereby interfering with thermohaline circulation. However, closer inspection of various facets of this theory has led many scientists to reject the theory. Fossil bones that contain the proposed meteorite fragments would all have to date from the same time frame in order to fit the theory, but this appears not to be the case. In fact, some of the bones in

question date to as much as 20 000 years BP (Dalton, 2007). A study by Paquay et al. (2009) found that terrestrial and marine sediments dating to the Bölling–Allerød/Younger Dryas boundary zone did not contain evidence of enriched extraterrestrial elements, such as iridium. Finally, Daulton et al. (2010) examined sediment samples from this time interval, looking for nanodiamonds. What they found instead were graphenes and graphene oxides, which they claim have been misidentified as nanodiamonds by Kennett and co-workers. Graphenes, a natural component of charcoal, occur in carbon spherules that are found throughout late Pleistocene and Holocene sediments. The weight of the evidence thus appears to negate the bolide impact theory of megafaunal extinction.

Can We Find the Smoking Gun?

The indisputable evidence for human-caused extinction of megafauna during the late Pleistocene, the so-called ‘smoking gun’ (or perhaps ‘blood-dripping spear’ would be a better metaphor), will probably never be found. There are several reasons for this. (1) Both the faunal and archaeological evidence are fragmentary in nature. We will never have a complete picture of what happened. This will always leave room for debate. (2) The dating of events will never be exact. Radiometric dating is the only way to date most paleontological or archaeological sites, and all radiometric dates come with uncertainties. In this sense, they are not true ages, as one would get from counting back annually layered sediments or tree rings. They remain age estimates, plus or minus centuries of time (when dealing with ages that are tens of thousands of years before present). (3) The early peoples of all the inhabited continents were hunter–gatherers who were mostly nomadic in lifestyle. They left pitifully little evidence of their occupation in the first place; what remains *in situ* after tens of thousands of years of decomposition, erosion, reworking of sediments, etc., will always be just a tiny fraction of the original material, be it mammal bones or human artifacts.

One scenario that would seem to fit the most facts might be a *coup de grâce* model. In this model, human predation contributes to the demise of the Pleistocene megafauna, to some degree. Indeed, the very nature of the megafauna – slow to mature and reproduce, with limited capacity to recover numbers rapidly following any perturbation – may only have needed a modest increase in human hunting to deliver the final blow. Science has yet to determine the extent of human influence on megafaunal extinction, but it seems most likely that humans played a larger role in some regions than in others. The modeling efforts of Alroy (2001) and Brook and Bowman (2002) were at least more dispassionate attempts to deal with the data in hand. In the coming decades, we may begin to approach a consensus, but it seems very doubtful that the definitive answers will ever be obtained.

This article is reproduced from the previous edition, volume 4, pp. 3197–3202, © 2007, Elsevier B.V.

Introduction

These well-preserved Ice Age (Pleistocene about 2 Ma to 10 ka) mammal specimens are the ‘crown jewels’ of their kind. Along with a few closely observed, beautifully executed depictions of Paleolithic cave art, they give us the best idea of the appearance of the now-extinct mammals.

The mummies have also yielded important information on: (1) taxonomic relations and dispersal history through the study of ancient DNA; (2) soft tissue structure; (3) paleodiet based on gut contents and associated feces; (4) paleopathology; (5) parasites; (6) predators and scavengers through the study of tooth-puncture marks in the skin and gnaw marks on the bone; and (7) paleoclimatic evidence inferred from plant remains in gut contents, ground squirrel nesting grasses, fecal pellets, and seed caches, as well as from the nature of enclosing sediments.

At least 16 species of Ice Age mammals have been mummified: woolly mammoth, Shasta ground sloth, Jefferson’s ground sloth, Patagonian ground sloth, woolly rhinoceros, Yukon horse, steppe bison, helmeted muskox, Harrington’s mountain goat, caribou, giant moose, black-footed ferret, collared pika, snowshoe hare, arctic ground squirrel, and vole. Among the best of these specimens are: (1) ‘Dima,’ a 40-ka-old baby woolly mammoth from Siberia; (2) a 10-ka-old Shasta ground sloth from New Mexico; (3) ‘Blue Babe’ a 36-ka-old steppe bison from Alaska; (4) an 18-ka-old subadult helmeted muskox also from Alaska; (5) a woolly rhinoceros from Ukraine; and (6) a 40-ka-old black-footed ferret from Yukon.

Most are preserved by a type of freeze-drying in frozen ground (permafrost) of Siberia, Alaska, and Yukon, and date from 50–25 and 15–10 ka. Presumably this is because extra moisture available during those warmer periods of the last glaciation allowed a quicker covering of the carcasses by melted, near-freezing sediments. The sloths and mountain goats were preserved in cave deposits – perhaps dry air and relatively constant temperature in the caves were mainly responsible for such good preservation. Woolly rhino and woolly mammoth carcasses from Starunia, Ukraine seem to have been ‘pickled’ in salty groundwater and coated by a mineral wax.

Where were the mummies found? How complete were they? How old were they individually and geologically? How were they preserved? These are a few of the questions commonly asked, that will be dealt with under the following categories: (1) circumpolar frozen fauna, (2) United States cave fauna, (3) Patagonian cave fauna, and (4) European ‘pickled’ fauna.

Circumpolar Frozen Fauna

Woolly Mammoths (*Mammuthus primigenius*)

The widely known mummies of Siberian woolly mammoths spring to mind – especially the Berezovka mammoth, one of

the earliest iconic finds made about 1900 by Lamut tribesmen on the Berezovka River; and ‘Dima,’ found in 1977.

The Berezovka mammoth was surprisingly well preserved, but had undergone some decomposition, as have most of the specimens (Lister and Bahn, 1994, pp. 44–45). Carnivores had eaten parts of the exposed head and several bones were broken. It had food between its massive molar teeth, and the nature of the muskox-like hair, the relatively short tail, and thick (90 mm) body fat were noted.

‘Dima’ (Figure 1), the frozen mummy of a young male, was found by a placer gold miner using a bulldozer on a terrace of the Kirgiliakh River, a tributary of the Kolyma River north of Magadan, Russia (Vereshchagin and Mikhelson, 1981). The carcass was intact and very little decomposition had occurred before the body was frozen. He may have become mired in a mud sink (Guthrie, 1990, figure 1.7). Judging from his size and degree of tooth eruption, Dima was about 4 months old. Several radiocarbon dates on tissue indicated that he had died during a relatively warm period of the last glaciation some 40 ka. Plant remains found with the carcass indicate that he had occupied a dry, grassy landscape with some trees near the valley bottom. ‘Dima’ is displayed beside the Berezovka mammoth in the Zoological Museum at St. Petersburg, Russia.

Several other Siberian woolly mammoth carcasses are known. One was found on a small tributary of the Khatanga River in 1977 (Vereshchagin and Nikolaev, 1982). It was probably an adult male about 50 yr old according to the degree of wear on its third molar, its large tusks, and body. Some skin remained on the head, including parts of the trunk and entire left ear. Radiocarbon dates indicate that the animal died about 50 ka. The carcass had decomposed and had been heavily scavenged. Another carcass was found on the Shandrin River in 1971. It was dated to between 42 and 32 ka and was notable for its well-preserved gut contents. Plants from the stomach were: 80% herbs (mainly grasses), 15% woody plants, 1% mosses, 1% heather leaves, and 5% unidentified (Gorlova, 1982). The dominance of grasses is similar to the gut contents of other mammoths suggesting an abundance of grasses in the mammoth habitat (Mammoth Steppe). Other woolly mammoth carcasses from Asia include: (1) ‘Mascha’ a young (about 4 months old) female from the Yamal Peninsula dating to about 39 ka (Mol and van Essen, 1992, p. 117; Lister and Bahn, 1994, pp. 46–47); (2) the Late Glacial (about 10 ka old) Yuribei mammoth, a 12-yr-old-female discovered from the Yuribei River in 1979 (Mol and van Essen, 1992, p. 114); (3) the Taimyr mammoth, an adult male (about 45 yr old) found on the Taimyr Peninsula, Siberia in 1948 (Mol and van, 1992, p. 113); (4) the Fishhook mammoth, an adult male 20.6 ka partial carcass from the Upper Taimyra River found in 1990 that had been grazing on moist grassy (98% Poaceae) tracts on the Taimyr Peninsula (Mol and Kahlke, 2004); (5) Adams mammoth near the mouth of the Lena River; (6) a carcass

Figure 1 Left side of the carcass of the baby mammoth (*Mammuthus primigenius*) 'Dima' from frozen ground on a terrace of the Kirgiliakh River northeastern Siberia, Russia (Zoological Institute, St. Petersburg).

from the Liakhov Islands; (7) a carcass from Sanga-Yurakh (see map in [Lister and Bahn \(1994\)](#), pp. 154–155), and (8) a 41 ka carcass of a well preserved baby collected in 2004 at the Olchan Goldmine in Oymyakonsky Ullus, Yakutia (D. Mol, Personal Communication 2006).

In 1948 a partial carcass (head and attached left leg) of a baby mammoth named 'Effie' was found at Fairbanks Creek, Alaska. It was radiocarbon dated to about 21 ka and may have died in its first year, according to its estimated shoulder height of 1 m. A mummified mammoth foot was also discovered at this site in 1940 ([Guthrie, 1990](#), figure 1.26).

There are stories by workers on the gold dredges near Dawson City, Yukon of excavated mammoth carcasses, but the only evidence I have seen during the collection of Pleistocene mammal remains in that area for about 30 years is a mammoth eye socket with attached shreds of dried flesh.

Woolly Rhinoceros (*Coelodonta antiquitatis*)

Woolly rhino mummies are known from frozen deposits in Siberia, as well as from petrochemical seeps in Ukraine. The Churapcha rhino was found in 1972 by a villager digging a cellar in a small settlement on the Lena–Amga interfluvium ([Lazarev, 1977a](#)). In 1971 an entire carcass was found on the Vilyuy River, but only the head and two legs were saved. Another carcass was discovered on the Kahlbuy River (middle Yana drainage) in 1877 ([Sutcliffe, 1985](#); [Guthrie, 1990](#)).

Horse (*Equus lambei* and *Equus* sp.)

Several carcasses of horses are known from the circumpolar regions. Radiocarbon dates on the Selerikan horse, a mature male, indicate a geological age between 39 and 35 ka ([Lazarev, 1977b](#)). It was found in 1968 on the Selerikan River (near the upper part of the Indigirka River), Siberia. The body was well preserved, missing only the head and neck. Perhaps it had been

mired up to its neck, and the head and neck were removed later by predators or scavengers ([Guthrie, 1990](#), figure 1.12). The body was found from below by drift gold miners who unknowingly at first used the lower hind legs to hold cables and lanterns! Pollen found in the horse's intestinal tract suggested a late-summer death. The hair was reddish brown with a dark mane, tail and legs, and the underside was yellowish to white.

This was not the first horse mummy from Siberia. In 1878, a white horse carcass thawed from frozen ground on the Yana River was not collected. Further, a mummified mare containing a large embryo, found on the upper Indigirka River, was excavated in 1950, but only a part of it was saved for study ([Lazarev, 1977b](#)).

A partial carcass of an adult Yukon horse (*Equus lambei*) was found by placer miners at Last Chance Creek near Dawson City, Yukon ([Harington and Eggleston-Stott, 1996](#)). It consisted of a right foreleg with dried flesh, skin and some dark lower-leg hair, the hide (from ear to tail) with tail, mane, body hair, and gut contents. The upper foreleg bone had been gnawed by medium-sized predators or scavengers, possibly wolves. A radiocarbon date of about 26 ka indicates that it had died during a relatively warm period of the last glaciation. Its grayish white body hair, mane, and tail (like the Yana River horse carcass) suggest that it died in winter. Both Last Chance Creek and Selerikan specimens are related to caballine horses.

In nearby Alaska, three partly preserved horse legs were collected from frozen ground in the Fairbanks area ([Guthrie, 1990](#), figure 1.19). During 1983, a horse skull, radius, and forefoot with hoof, all tissues still attached, was recovered from frozen silt along the Titaluk River, Alaska. Hoof keratin yielded a radiocarbon age of about 17 ka. The structure of the hoof suggests that the animal survived on winter range characterized by shallow snow and low forage quality but high quantity. The rate of hoof growth and wear suggests a relatively sedentary existence and little digging through snow for food ([Guthrie and Stoker, 1990](#)).

Steppe Bison (*Bison priscus*)

Two of the best carcasses of this species are from the Fairbanks area of Alaska. A nearly complete mummy, called 'Blue Babe' because of the bluish iron oxide (vivianite) coloring its surface, was discovered by placer miners near Pearl Creek in 1979. Evidently, it was killed by lions (*Panthera leo atrox* or *P. l. spelaea*) about 36 ka. It was restored and is on display at the University of Alaska Museum, Fairbanks (ML [Guthrie, 1988](#); RD [Guthrie, 1990](#), figure 11.5).

A carcass from Dome Creek ([Figure 2](#)), also a large mature male, was discovered in 1952 and was about 7 yr old at death. Radiocarbon dating indicated that it had died about 28 ka ([Guthrie, 1990](#)). A less complete carcass of a female bison, also about 7 yr old, was found on Fairbanks Creek in 1952. Two partial bison legs are known from Cleary and Goldstream creeks near Fairbanks ([Guthrie, 1990](#)).

It is not uncommon to find steppe bison skulls with well-preserved horns sheaths from Yukon Pleistocene deposits in both Dawson City and Old Crow areas. In addition, a well-preserved forefoot covered by dried skin was collected at Hunker Creek, Dawson City area in 1988.

Figure 2 Right side of a partial carcass of an extinct steppe bison (*Bison priscus*) from frozen ground on Dome Creek near Fairbanks, Alaska. The collector of most of the Alaskan Pleistocene carcasses, including this one, the late Otto Geist, is examining a fragment of hide (T. L. Péwé).

A partial carcass of a young female bison found on the Indigirka River is the only one known from Siberia. She died about 30 ka (Flerov, 1977).

Helmeted Muskox (*Bootherium bombifrons*)

A nearly complete carcass of a subadult (about 2.3 yr old according to tooth development) was found in frozen organic silt by gold miners at Fairbanks Creek, Alaska, and collected by Otto Geist (see Figure 2). It is the only known mummy of the helmeted muskox – a native of North America that never reached Eurasia. It lacks the horncores, and the right side of the trunk has been damaged. Radiocarbon dates indicate that the animal lived at a time near the Last Glacial Maximum, about 18 ka. Hair on the lower limbs is darker than that of the living tundra muskox (*Ovibos moschatus*). The limbs of this specimen are longer and relatively more slender and the tail is longer than are those characters in the tundra muskox. Gut contents were preserved but have not been analyzed (McDonald, 1984).

Giant Moose (*Alces latifrons*)

Several partial carcasses of this extinct moose have been collected in Alaska: (1) a yearling male, discovered on Little Eldorado Creek in 1940, had thick body fat and an attached antler suggesting that it had died in fall or early winter; (2) a young female was found on the same creek near Fairbanks in 1942; and (3) fragments of at least two giant moose carcasses were found at Livingood, Alaska in 1980; one of these fragments yielded a radiocarbon age of 32 ka (Guthrie, 1980, figures 1.23–1.25).

Caribou (*Rangifer tarandus*)

Mummified lower legs have been collected from Upper Cleary Creek near Fairbanks, Alaska in 1945 and Tofty, Alaska in 1948 (Guthrie, 1990, figure 1.19).

Figure 3 Left side of the carcass of a 40-ka-old adult male black-footed ferret (*Mustela nigripes*) from Sixtymile, Yukon, Canada (C. R. Harington).

Black-Footed Ferret (*Mustela nigripes*)

The most spectacular of Yukon Ice Age mammal carcasses is a black-footed ferret (Figure 3) – now extinct in Yukon and nearly so in North America. It is of a young adult male, radiocarbon dated to 40 ka, whose fur differed little in color and pattern from recently caught museum specimens. He was originally collected by ‘Molly,’ a placer miner’s dog at Sixtymile, Yukon in 1984! An X-ray image showed that he had remains of his last meal in his intestine – probably a vole (*Microtus*) according to analysis of hair extracted from the gut (Youngman, 1987). A less complete mummy of an adult female black-footed ferret from Hunker Creek near Dawson City, Yukon was collected in 1987. She yielded a radiocarbon age of about 30 ka (Youngman, 1994).

Arctic Ground Squirrel (*Spermophilus parryi*)

This carcass was picked up by a curious placer miner on Glacier Creek in the Sixtymile area, Yukon in 1981. It became a topic of local conversation, and, being round, was called ‘the moon-egg.’ It was finally identified as an Arctic ground squirrel when rust-colored hair began appearing through the micaceous silt that covered it and part of a skull was seen through a crack in the skin. It consisted of a complete individual curled up nose to tail, that probably had died during hibernation. It yielded the oldest finite radiocarbon age known for any Yukon Ice Age mammal – 47 ka (Harington, 1984; Walker, 1984).

Another Arctic ground squirrel carcass was collected in 1935 at Eva Creek in the Fairbanks area of Alaska (Guthrie, 1990, figure 1.26).

Collared Pika (*Ochotona princeps*)

This carcass was collected at Chatanika, Alaska, just north of Fairbanks in 1933. It has some hair around the digits and the body is flecked with blue vivianite. The occurrence of this Alpine species in central Alaska corroborates the idea that Alpine environments extended into drier, steppe-like lowlands during glacial times (Guthrie, 1973, 1990, figure 1.26).

Snowshoe Hare (*Lepus americanus*) and Vole (*Microtus*)

Other Alaskan mummies include a virtually complete snowshoe hare from Fairbanks Creek collected in 1949, and an unspecified vole carcass (Guthrie, 1990, figure 1.26).

United States Cave Fauna

Shasta Ground Sloth (*Nothrotheriops shastensis*)

The best specimen of this species is from Aden Crater, New Mexico (Lull, 1929). It consists of a complete skeleton with ligaments and other dried soft tissue, including patches of skin and hair. In addition, hair, pieces of skin, claws with their sheaths, and even intervertebral disks have been found in other caves such as Rampart Cave, Arizona (Wilson, 1942; Harrington, 1972) and Gypsum Cave, Nevada (Stock, 1931; Harrington, 1933; McDonald, 2003, figure 1.5).

Jefferson's Ground Sloth (*Megalonyx jeffersonii*)

Dry, soft tissue of this species has been recovered from three individuals in Big Bone Cave, Tennessee (Mercer, 1897; McDonald, 2003, figure 1.2). Some of the bones retain cartilage on the articular surfaces, as well as dried ligaments, and one claw retains the keratinous nail.

Harrington's Mountain Goat (*Oreamnos harringtoni*)

Soft parts of this small, extinct mountain goat, such as horn-sheaths and a well-preserved forefoot have been collected from Rampart Cave, Arizona and at other caves in the western United States (Harrington, 1972; Mead and Lawler, 1994).

Patagonian Cave Fauna

Patagonian Ground Sloth (*Mylodon*)

Mummified ground sloth remains have been found in South America. In 1896, Herman Eberhardt, a local farmer, found a piece of dried skin with short yellow-brown hair in the great cave of Ultima Esperanza in Chile (Patagonia). The following year another skin fragment was discovered by F. P. Moreno, hanging on a nearby tree. The small nodules of bone in the skin suggested that it belonged to the extinct ground sloth *Mylodon*, known to have occupied the cave (Sutcliffe, 1985, figure 12.12). The cave also contains thick deposits of ground sloth dung, keratinous claws, and clumps of hair (D. Schreve, Personal Communication 2006).

European 'Pickled' Fauna

Woolly Mammoth (*Mammuthus primigenius*)

At Starunia in southwestern Ukraine in 1907, a woolly mammoth carcass was found at a depth of 43 m in subsoil filled with veins of kerosene. Some decomposition had occurred before the tissues became embalmed, but this was the only mummified mammoth found outside the circumpolar permafrost regions. Like the woolly rhino mummies from the same site, it had been naturally 'pickled' in a petrochemical seep associated with salt deposits and surrounded by the mineral wax ozocerite. The skeleton was well preserved and the skin still supple, but the hair was firmly attached to the surrounding sediment (Lister and Bahn, 1994, p. 57).

Woolly Rhinoceros (*Coelodonta antiquitatis*)

Besides the carcasses reported from frozen ground in Siberia, 'pickled' specimens are known from the Ukraine. The most famous of all woolly rhino mummies are those from Starunia (formerly in Poland, now in Ukraine) that were discovered in 1907 and 1929 (Guthrie, 1990, figure 1.13). Like the mammoth reported above, they were 'pickled' by a saline solution and coated by ozocerite. Plant remains found with the specimens included dwarf birch and small-leaved willows, showing that tundra conditions colder than present prevailed when the rhinos died (Sutcliffe, 1986, p. 40). Guthrie (1990) notes that Siberian woolly rhinos fed mainly on grasses.

Preservation of Frozen Mummies

In 1970, Reginald Harris, a specialist in freeze-drying at the British Museum (Natural History), now The Natural History Museum in London, concluded that the Patagonian ground sloth (*Mylodon*) skin had been naturally freeze-dried at a time of very cold climate (Sutcliffe, 1985, figure 12.13). That too was my conclusion regarding the preservation of Yukon carcasses. Guthrie's (1990, p. 22) hypothesis regarding the preservation of the steppe bison 'Blue Babe' and the Siberian mammoths is more sophisticated. It involves water withdrawal due to the presence of segregated ice surrounding the mummies that dehydrates them in the frozen ground. He further states that underground frost mummification should not be confused with freeze-drying that occurs when a body is frozen and moisture is removed by sublimation, a process accelerated by a partial vacuum.

The Early History of Ancient DNA Research

In 1984, [Higuchi et al. \(1984\)](#) realized a landmark in molecular biology: the molecular cloning through bacterial vectors of fragments of the mitochondrial cytochrome *b* gene of the quagga (*Equus burchelli quagga*). The potential of this approach was instantly appreciated, at least by the popular press, as an exciting new way to study the recent past. The enthusiasm stemmed from the fact that the last quagga had died in an Amsterdam zoo in 1883, and the subspecies declared extinct. The source material for the study was a scrap of tissue that had come to light during remounting of the Amsterdam specimen, which had been on display for more than a century. Higuchi et al. had conclusively shown that ‘ancient’ DNA (aDNA) could survive in preserved tissue for appreciable amounts of time post-mortem.

Due to the difficulty of the bacterial cloning techniques employed in these early studies, new findings were published only sporadically between 1984 and 1987, for example, extraction of nucleic acids from an ancient Egyptian mummy ([Paabo, 1989](#)), which supported the idea that human genes could be similarly accessible to molecular techniques.

Polymerase Chain Reaction

The scope of the field of aDNA research was to change permanently with the advent of polymerase chain reaction (PCR) ([Mullis et al., 1986](#)), a new molecular biology technique that allowed for the exponential production of millions of copies of a targeted region of DNA from as little as one template molecule. PCR is an enzymatic reaction in which a series of heating and cooling cycles exponentially increase the number of DNA strands in an extract, resulting in rapid amplification of the

target DNA sequence. Specificity is obtained by the use of pairs of short single-stranded DNA molecules (primers), complementary to the sequences at either end of the region to be copied, which ‘prime’ the action of the polymerase enzyme.

The exceptional sensitivity of PCR is advantageous for aDNA research, as the initial copy number of DNA sequences is often low in ancient samples. However this sensitivity, combined with the minute amounts and degraded nature of surviving DNA, results in an exceptional risk of contamination, as even trace amounts of modern DNA will preferentially amplify and outcompete an ancient template.

The invention of PCR led to a significant increase in the number of aDNA publications, due to the ease with which DNA could be amplified. Long-standing evolutionary questions on the specific relationships between recently extinct creatures and their presumed relatives were among the first to be addressed. Often these studies merely corroborated pre-existing theories, as when preserved tissue from the marsupial thylacine (*Thylacinus cynocephalus*) was used to confirm its relation to the Australian dasyuromorphs ([Thomas et al., 1989](#)) and bone sampled from mammoth showed it to be a member of the Elephantidae ([Hagelberg et al., 1994](#); [Hoss et al., 1994](#)).

Following on from these early studies, a series of increasingly extreme claims for geologically aDNA were made, for example, DNA from Miocene plant fossils ([Golenberg et al., 1990](#)), Oligomocene termites in amber ([Desalle et al., 1992](#)), and Cretaceous dinosaurs ([Woodward et al., 1994](#)). The DNA preservation levels claimed for these studies seemed incompatible with the known properties of the chemical structure of DNA ([Lindahl, 1993](#)) and it was clear that the burgeoning discipline was in need of some critical input. As a result, a series of reviews were published focusing on the necessity of reproducibility in aDNA, as well as the probability of DNA

survival over geological time (e.g., [Lindahl \(1993\)](#) and [Paabo \(1989\)](#)). These reviews eventually led to a broad consensus regarding the burden of proof for publishing aDNA research, and in turn to the formulation of several criteria checklists for aDNA research consisting of various permutations of the following requirements: physically separated work areas (to prevent spread of modern amplified DNA into ancient specimens), sterile equipment, multiple negative controls, evidence of authentic PCR behavior (i.e., inverse relationship between amplified fragment length and successful amplification), quantitation of starting template number, and the demonstration of reproducibility. The appropriateness of each of these procedures, however, should be evaluated on a case-by-case basis (see [Gilbert et al. \(2005\)](#)).

Sources of Ancient DNA

DNA is preserved in a variety of plant and animal remains, including leaf tissue, seeds, bone, hair, teeth, skin, and fecal/urine waste products. While an organism is alive, an array of enzymes serves to maintain DNA by repairing broken and damaged strands. Immediately following the death of the organism, this system stops, and damaged DNA remains unrepaired. As cellular processes cease and bacterial infection spreads, autolytic endonucleases that normally degrade foreign bodies, DNA, and unwanted products are released from control, causing further DNA degradation. Once these enzymes are either destroyed or deactivated, the rate of decay is considerably slowed. However, DNA will continue to decay spontaneously, mainly due to exposure to various forms of radiation, and the biochemical processes of hydrolysis and oxidation ([Hoss et al., 1996](#); [Lindahl, 1993](#)).

Radiation-induced damage inhibits enzyme amplification by causing complete double-strand breakage of the DNA backbone. DNA fragments may then be cross-linked with proteins and/or broken down into small fragments. Hydrolysis causes depurination/depyrimidation of the nucleotide bases and cleavage of base-sugar (N-glycosal) bonds, creating single-strand nicks in the DNA sequence. Deamination of cytosine to uracil, and depurination, or loss of the purines (adenine and guanine), are the most common types of hydrolytic damage. Oxidative damage, caused by the direct interaction of ionizing radicals with the DNA, is most commonly seen as modifications of sugar residues and of the pyrimidines (cytosine and thymine) to hydantoins. Oxidative damage can cause baseless sites (as in hydrolytic damage) and the formation of interand intrastrand cross-links, which can block the processivity of DNA polymerases used in PCR. A small proportion of damage events do not hinder replication, but generate miscoding lesions. These may manifest as base modifications in a PCR-amplified sequence, changing the appearance of the DNA template and potentially misleading haplotype analyses ([Gilbert et al., 2003](#)).

Fortunately, for aDNA research, the processes of DNA decay can be considerably slowed in certain environments. Although a trend toward lower DNA content with burial time has been observed ([Lindahl, 1993](#); [Tuross, 1994](#)), the impact of the environment on DNA preservation is by far the most important factor in determining the amount of retrievable DNA in a

sample (e.g., [Gilbert et al. \(2003\)](#)). The best environments for long-term preservation of DNA involve particularly cold or rapidly desiccating conditions, where the samples are protected from exposure to UV light. DNA has been shown to survive in samples kept in museums for on the order of tens to several hundred years. Cold, dry environments such as the Arctic or high altitude caves have proved to be particularly conducive to long-term preservation of DNA ([Shapiro and Cooper, 2003](#)). Freezing, shortly after death, limits the amount of DNA damage from enzymes intrinsic to the cell as well as subsequent bacterial or fungal degradation ([Lindahl, 1993](#)). However, [Guthrie \(1990\)](#) has observed that an intact carcass generates enough heat during decomposition to limit freezing, and this may explain why the DNA yield from mummified permafrost specimens is generally much lower than from isolated bones. For this reason, it may be possible that the best DNA samples would come from bones that have been rapidly defleshed after death, preventing bacterial growth in close proximity to the bone. Biochemical data suggest, however, that even in optimal conditions, the upper limit for DNA survival will be on the order of only a few hundred thousand years ([Lindahl, 1993](#)).

Mitochondrial DNA (mtDNA), rather than nuclear DNA, is most often the target in aDNA research, as the mitochondrial genome is present in eukaryotic cells at a much higher copy number than is the nuclear genome, resulting in a greater probability of amplifying intact mtDNA fragments. Mitochondria are organelles found within the cytoplasm of a cell that are responsible for the Krebs cycle and the electron-transport chain, and therefore for the cell's energy production. The number of mitochondria in a cell varies depending on the cell's energetic requirements, and can range from several hundred to several thousand copies per cell. Each mitochondrion has one to four circular copies of mtDNA and exhibits high rates of nucleotide substitutions compared with nuclear DNA ([Moritz et al., 1987](#)). Additionally, mitochondria are maternally inherited, and therefore do not undergo recombination. These factors make mtDNA particularly useful in studies of population genetic structure and phylogenetic relationships among species.

Throughout the process of evolution, partial copies of the mitochondrial genome transfer to the nucleus, resulting in pseudocopies of the mitochondrial DNA sequence referred to as nuclear mitochondrial copies or numts. Fortunately for aDNA research, the number of real mitochondrial sequences is large, based on high starting copy number and similar probabilities of DNA damage and decay, compared to the number of amplifiable numts, so, in most instances it is only possible to amplify the mtDNA sequence. Exceptional preservation combined with a disproportionately large number of numts, however, have made distinguishing the real mtDNA sequence difficult in some taxonomic groups. For example, numts not only caused significant problems in the mammoth study mentioned above, but also call into question the only mastodon sequences reported to date ([Yang et al., 1996](#)).

Recent Directions in Ancient DNA

The parallel increase in the complexity of questions addressed by ancient DNA and the sensitivity of molecular techniques

paved the way for many groundbreaking studies in the 1990s. The primary goal of aDNA research has moved away from sample identification and taxonomy toward phylogeography and demography, which we discuss in turn below. Examples are taken primarily from work conducted on late Pleistocene faunal remains.

Although originally mooted as a potential application of the technology, species-level identification of bone specimens that are incomplete or too badly damaged to classify morphologically has seen little application at present. The financial cost of analyses makes this an impractical option for routine use. However, it remains possible that, when an accurate identification is vital in determining the presence/absence of a species from a crucial site or time period, ancient DNA might be employed as an informative tool.

Considerably, more aDNA research has focused on resolving phylogenetic relationships of extinct vertebrates. Recent examples include the dodo (*Raphus cucullatus*), cave lion (*Panthera spelaea*), sabretooth cats (*Smilodon* and *Homotherium*), cave bear (*Ursus spelaeus*), ground sloths (*Nothrotheriops* and *Myiodon*), giant deer (*Megaloceros giganteus*), and woolly rhino (*Coelodonta antiquitatis*), each with molecular results that broadly corroborate previous morphological analyses. Two studies from New Zealand, however, demonstrate that unexpected relationships are sometimes discovered. The kiwi (*Apteryx* spp.) and extinct moa (Aves: Dinornithiformes), for example, were not found to be as closely related as was previously assumed, a discovery which necessitated reinterpretation of the scenario by which these two species colonized New Zealand (Cooper et al., 1992). It was also discovered that the extinct New Zealand giant eagle, *Haarapagornis moorei*, was very closely related to an Australian genus of little eagles, suggesting an unusually rapid increase in body size (Bunce et al., 2005).

One of the most remarkable accomplishments of aDNA research has been the amplification of mitochondrial control region sequences from the Neanderthal-type specimen (Krings et al., 1997) and subsequent analysis of Neanderthal remains from Mezmaiskaya (Ovchinnikov et al., 2000) and Vindija (Paunovic et al., 2001). To date, ten different Neanderthal specimens have had sections of control region amplified (Beauval et al., 2005), all producing sequences that group together to the exclusion of modern humans.

Since the 1980s, there has been a decided increase both in the amount of molecular data that can be amplified from ancient specimens and in the complexity of statistical models capable of examining phylogenetic relationships between extinct organisms. These developments have made it possible for aDNA to address more sophisticated evolutionary questions, for example, at the level of the population rather than the species. Adding ancient data to population genetic analyses makes it possible to directly observe how populations change through time, and potentially to correlate genetic change with changes in climate or habitat.

The majority of population-level aDNA research has focused on the late Pleistocene (<100 ka BP). The widespread abundance of the late Pleistocene megafauna means that traditional paleontological approaches can be applied globally, rather than to a few key localities. Skeletal morphology, however, is more often applied to the differences between species, rather than providing information about within-species changes in population

structure (see, however, Polly (2003)). Additionally, high-resolution dating techniques, such as radiocarbon dating, are widely employed to provide a temporal scale for the analyses. Dating of skeletal remains, however, is generally insufficient to provide a statistical basis for demographic change, as it simply records the presence of a particular taxon at one point of time.

To address these problems, an important complementary approach has been the use of phylogeography, or the study of spatial patterns of genetic diversity within and between species. Phylogeographic reconstruction can be used to infer the geographic origin of populations and subspecies, the course of range expansions, and the presence of genetic bottlenecks. The timing of these can be estimated using a molecular clock, which is normally calibrated by reference to species divergences attested to in the fossil record. However, phylogeography has traditionally been limited by the need to infer past demographic events from data derived from modern samples. Contemporary patterns of genetic variation are the result of a cumulative series of demographic events, making it difficult to resolve past events if histories are complex. Moreover, little or no signal of demographic events can be observed if they pre-date genetic bottlenecks.

Ancient DNA methodology makes it possible to recover incorporating sequence data directly from radiocarbon-dated bones, providing a mechanism to circumvent these problems. A key example is found in one intensively studied group, brown bears, and reveals surprisingly complex patterns of localized extinctions, replacements, and changing biotic interactions in eastern Beringia during the late Pleistocene (Barnes et al., 2002; Leonard et al., 2000). In this instance, a number of genetic events have generated a relatively simple late Holocene phylogeographic distribution, such that studies focusing exclusively on the genetics of modern populations could easily be misconstrued. Despite the dynamic history, an unexpected degree of phylogeographic structure is observed in late Pleistocene mitochondrial haplotypes of brown bears, suggesting that some form of temporal and spatial regionalism has existed within these populations for a considerable time. Changes to this relatively rigid phylogeographic structure enable the timing of significant environmental events to be inferred, and reveal the location and timing of possible dispersal routes between Beringia and the landmasses south of the ice sheets. Importantly, the timing of these late Pleistocene genetic events do not appear to be tightly related to major climatic changes, and it appears, in the bears at least, that environmental effects may be secondarily mediated through interaction with competitors or other unknown factors (Barnes et al., 2002).

A further development in the exploitation of aDNA sequences has been the inference of demographic change through time. In a study of small mammal remains from a single locality in Wyoming, Hadly and colleagues have utilized coalescent simulations to address questions about the relationship between climate, population size, and genetic diversity (Hadly et al., 2004). This work bridges a gap between the use of mtDNA sequences as population markers and the application of models which consider molecular change through time to derive demographic and evolutionary parameters. These types of models, coupled with heterochronous (different age)

sequence data, have been most extensively applied to studies of viral populations sampled over timescales of months to decades (Drummond et al., 2003).

A limitation of this type of analysis is that, in order to have statistical power, a large amount of genetic diversity must be present in the population being analyzed. This is the case where mutation rates are high (e.g., viruses) or where the amount of time over which the samples are collected is long, as with aDNA. Initial studies applying this approach to data from Holocene Adelie penguin colonies allowed estimation of the mutation rate of the mitochondrial first hypervariable region (HVRI), independent of fossil calibration (Lambert et al., 2002). More recently, Shapiro and colleagues have completed a study of Pleistocene bison, generating sequence data for over 600 bison ranging in age from modern to >65 ka BP (Shapiro et al., 2004). The geographical focus of this study is eastern Beringia (Yukon, Canada and Alaska), but samples from Siberia and the continental United States develop the patterns of movement across the Bering land bridge, and south through the ice-free corridor. They move from this description of late Pleistocene population dynamics to the use of a Bayesian Monte Carlo Markov chain (MCMC) method to derive rates of mutation and dates of divergence from the data, and investigate changes in the effective population size through time. This latter analysis shows the power of the technique to resolve a complex pattern of demographic change: population expansion up to around 30 ka BP, decline through the end Pleistocene and Holocene, subsequent expansion at around 3 ka BP, and an additional abrupt population crash in the last few hundred years. As the experimental and statistical techniques for dealing with aDNA data improve, the number of species for which such population-level analyses have been done will continue to rise, moving toward a much better picture of the late Pleistocene ecosystem.

Speciation and Evolutionary Trends in Quaternary Vertebrates

A M Lister, The Natural History Museum, London, UK

© 2013 Elsevier B.V. All rights reserved.

Introduction

The Quaternary is an ideal interval in which to study the origin of vertebrate species and their adaptations in the fossil record. The time intervals available (10^2 – 10^6 years) are of the order of magnitude at which such processes occur; there is a rich fossil record over a wide geographical area; and paleoenvironmental and dating studies allow one to put the evolving vertebrates into a chronological and ecological context. Recent reviews of the subject have been given by Lister (2004) and Blois and Hadly (2009). This article focuses on phenotypic evolution that can be traced through stratified sequences of fossils. In practice, at the current state of knowledge, this restricts available case histories to mammals. Moreover, the present review focuses on the continental landmasses and excludes hominins; evolution in hominins and on islands is treated separately. Molecular data, based on both modern and ancient samples, are increasingly complementing morphology-based studies of Quaternary vertebrate evolution, and some molecular studies relevant to Quaternary speciation processes in mammals and birds are mentioned here.

The principal evolutionary processes that can be traced in Quaternary mammals are: (a) speciation, that is, the multiplication of species by division of an ancestral lineage into two, known as cladogenesis; and (b) phenotypic change within a single lineage, especially when adaptive, known as anagenesis. An evolutionary trend is here taken to mean a net directional phenotypic shift observed across three or more time intervals. It is an accumulation of phenotypic change that may occur within a single species, or across a series of chronospecies.

Phenotypic changes within Quaternary fossil mammals have frequently been presented, often implicitly, as examples of 'gradualistic evolution,' that is, a series of ever-progressing 'transitional forms' linking nominal species. There are also many examples in the literature where the logic is inverted and fossil deposits are dated on the basis of the evolutionary 'level' of a particular mammal species, with an implicit assumption of a gradualistic underlying pattern. However, according to the 'punctuated equilibrium' model of evolution, most adaptive change is thought to occur during the relatively rapid process of species formation. Between speciation events, evolution is minimal. This model implies a strong linkage between phenotypic change and speciation, and downplays the role of anagenesis, long-term trends being driven instead by selection among differently adapted species (species selection: Gould and Eldredge, 1977).

In reality, theoretical considerations and the study of modern species show us that evolutionary rates are highly variable, so that no particular pattern of change has universal application, but has to be determined in each case from fossil samples dated independently of their 'evolutionary level' (Lister, 1992). Indeed, Darwinian natural selection would

predict complex variations of rate and pattern in the constantly changing environments of the Quaternary.

Studies of evolutionary change also need to take account of geographical effects, especially (a) spatial variation of phenotype and (b) dispersal. Most species today exist as a 'metapopulation' – a complex of geographically separated populations linked by restricted gene flow through migration. In the allopatric speciation model of Mayr (1963), one of these populations becomes partially or wholly isolated at the edge of the range of the parent species. The isolated population evolves new features in its local habitat and at the same time, or on subsequent recontact, becomes reproductively isolated from the parent. On invading the range of the latter, it may either displace it or coexist with it. Another model of evolutionary change that emphasizes geographical variation is Wright's 'shifting balance' theory (Levinton, 1988). Here, the parent species is divided into a set of partially isolated populations, each of which may evolve new features. Occasional gene flow between the populations allows these features to spread through the species as a whole. In a further model, the divergence of abutting populations without isolation (parapatric speciation) may occur if the species' ranges are large enough to allow selection to dominate over gene flow (Jiggins and Mallet, 2000). All of these models of speciation have a characteristic in common that novel morphological features appear in one area first and may then spread over a wider range.

Transferred into the fossil record at Quaternary timescales, these processes have predictable signatures that can be used to test between different models of evolution. The gradual transformation of one morphology into another through a chronological series of fossils, coincident in correlated samples across the geographical range, would suggest anagenetic evolution (transformation of a lineage without splitting) over a wide area. On the other hand, if change is found in a small area while elsewhere the ancestor remained little-changed, it would suggest that sampling is being done in the very area where an allopatric isolate is speciating (cladogenetic evolution). Sampling of later deposits over a wider area may then show the process of spread of the new form. A further important line of evidence is the finding that 'ancestral' and 'descendent' forms co-occur at a single time and place, implying that their ranges have come to overlap. This is inconsistent with purely anagenetic change and implies that a cladogenetic event has occurred, presumably outside the sampled area.

The question of whether speciation rates (or evolutionary rates in general) were elevated in the Quaternary, relative to earlier periods, is contentious (Lister, 2004; Blois and Hadly, 2009). Dramatic environmental changes will undoubtedly have exerted elevated and novel selection pressures on mammalian populations, although their cyclicity in the Quaternary may in some cases have checked significant directional change. The repeated expansion–contraction cycle of species' ranges

into and out of refugia would also have had population genetic effects that may in some cases have promoted speciation (Stewart et al., 2009).

The ideal requirements for demonstrating evolutionary processes in Quaternary mammals are statistical samples of fossils through finely stratified sequences, in correlated deposits across the geographical range, with excellent chronological control and paleoenvironmental proxy data. Only in rare cases are all of these conditions met. In the following account, selected examples illustrating aspects of speciation and evolutionary trends are presented.

Species and Subspecies Origins

The origin of familiar species is a topic of enduring fascination. Questions of interest include the location, time, and duration of a species' origin, the adaptive novelties that arose, and the environmental pressures that produced them.

In an approach to assessing the time required for speciation among Quaternary mammals, Lister and Rawson (2003) and Lister (2004) tabulated some published examples of divergence rates. Starting at the 'short' end of possible timescales, northern mammalian species occupying Beringia in the last glaciation provide a test case, as they were separated between Siberia and Alaska at the last flooding of the Bering Strait, about 10 ka (Elias et al., 1996). Many species today are found on both sides of the strait, for example, the arctic fox, *Alopex lagopus*, but no example of sibling species exists among the mammals, and even nominal subspecies pairs across the strait are often barely divergent: the duration of isolation was evidently too short. An interesting example has been provided by Fedorov et al. (2003) in their study of lemmings (*Lemmus*). This group shows strong phylogeographical division into four haplogroups (groups of related individuals based on mitochondrial DNA (mtDNA)) around the Holarctic, but a single haplogroup of one species, *Lemmus trimucronatus*, straddles the Bering Strait.

On a slightly longer timescale, incipient speciation can in some cases be traced within a single 100 ka Milankovitch cycle, as in shrews of the *Sorex araneus* complex in Europe. Two groups identified by Polly (2001) show not only morphological and genetic differentiation but also karyotypic differences, which appear to have accumulated between populations since the last interglacial.

In various other taxa, 'species pairs' occur on either side of the Bering Strait (Hoffmann, 1981), but events much earlier than 10 ka are implicated. Some of these species pairs are Quaternary in origin, for example, the lynx. This genus is represented by *Lynx lynx* in Eurasia and *Lynx canadensis* in North America, but the fossil form *Lynx issiodorensis* was spread across both continents in the early Pleistocene (about 1 Ma) and is a likely progenitor to both (Kurtén and Anderson, 1980), even though mtDNA divergence of 4% suggests a deeper coalescence of haplotypes, at about 3.2 Ma (Johnson and O'Brien, 1997). In this and many other examples, however, neither the precise timing nor the duration of the speciation process can be estimated from available fossils.

For several living species, mtDNA evidence suggests that diverging clades have survived several 100 ka Milankovitch climatic cycles, with extensive range changes, as well as the

formation of hybrid zones when the populations meet, yet without homogenization or losing their momentum toward speciation. Examples include the incipient red deer/wapiti species *Cervus elaphus*/*Cervus canadensis* (Lister, 2004) and various Siberian lemmings, *Lemmus* spp. (Jarrell and Fredga, 1993; Fedorov et al., 2003). Evidently, divergence leading to speciation can accumulate over several glacial-interglacial cycles.

Avise and Walker (1998), reviewing mtDNA divergence between intraspecific phylogroups of birds, similarly found a range of divergence dates from 75 ka to 4 Ma and concluded that Pleistocene conditions have played an active role both in initiating major phylogeographic separations within species and in completing speciations that had been inaugurated earlier. In a detailed study of southern skuas, Ritz et al. (2008) deduced that allopatric speciation on sub-Antarctic islands had been initiated during MIS 6 (about 200–140 ka) as the expanded ice cap reduced nesting and foraging sites on the Antarctic continent.

Turning to morphology-based studies of fossils, the bear family (Ursidae) provides a good example of adaptive speciation in the Quaternary (Figure 1). The bears that first appeared in Europe in the early Pleistocene, about 1.3 Ma (e.g., at Pietrafitta, Italy; Mazza and Rustioni, 1994), gave rise to three lineages. The first was the omnivorous brown/grizzly bear (*Ursus arctos*), now of broad Holarctic distribution. The other two became more specialized: one led to the largely vegetarian cave bear, *Ursus spelaeus*, and the other to the largely carnivorous, semiaquatic polar bear *Ursus maritimus*.

Fossils with cave bear characteristics first appeared in Europe in sites dated to about 1 Ma, such as Atapuerca TD4, Spain, and Vallonet, France (García, 2003), apparently by transformation of a regional population of the brown bear/cave bear stem lineage, while populations in Asia gave rise to the brown bear that later spread more widely (P. Mazza and N. García, personal communication). This is consistent with a recently obtained mtDNA split date between brown and cave

Figure 1 Schematic diagram of speciation in the Pleistocene brown bear lineage. P, Poolepynten; Pi, Pietrafitta; AV, Atapuerca and Vallonet (see text). NW–SE diagonal shading = evidence of 'cave bear' morphology. NE–SW diagonal shading = evidence of polar bear morphology. Approximate timescale in Ma on the right. Speciation date of cave bear based on fossils Pi and AV; speciation date of polar bear based on DNA evidence and known only within broad limits (see text).

bears of about 1–2 Ma (Lindqvist et al., 2010). Until recently, it was assumed that the cave bear lineage was limited to Europe as far as the Urals. Recent finds in the Altai, and even the Yana basin of NE Siberia, indicate a more widespread and complex biogeographic history (Knapp et al., 2009; Sher et al., 2011).

The polar bear, *U. maritimus*, has long been envisaged as having evolved in the middle Pleistocene from a coastal population of brown bears that took to feeding on marine mammals (Kurtén, 1964), but the fossil record is extremely poor. Mitochondrial DNA studies supported Kurtén's supposition, suggesting that the polar bear evolved from within the range of brown/grizzly bear populations. Initial molecular estimates of the date of divergence, based on mtDNA, ranged from 250 to 150 ka (Talbot and Shields, 1996; Barnes et al., 2002; Lindqvist et al., 2010). However, nuclear DNA suggests that the species pre-dates the modern diversity of brown bears, and separated within the Early to early middle Pleistocene, between 0.9 and 0.4 Ma (Edwards et al., 2011; Hailer et al., 2012). Lindqvist et al. (2010) described a mandible from Poolepynten, Svalbard, in the Arctic Ocean north of Norway, from a deposit of estimated age 130 ka, that shows polar bear morphology and an isotopic signature indicating a marine diet, indicating that the species' modern adaptations were in place by at least that date. The phenotypic and ecological separation of the two species has persisted despite evidence of occasional subsequent introgression (Edwards et al., 2011; Hailer et al., 2012).

The mammoth lineage (*Mammuthus*) also shows clear evidence of cladogenetic speciation, but as this was part of a complex process that led to directional evolutionary trend in the lineage, and it is described in the next section.

Evolutionary Trends

Bank Voles (*Clethrionomys*)

Small mammals (principally rodents) have provided many examples of evolutionary trends in the Quaternary, mostly followed in the dentition (Martin, 1984, 1993; Maul et al., 1998). Moreover, certain features are found to have evolved in parallel across many lineages – the most widespread being an increase in crown height, or hypsodonty, generally considered an adaptation to eating increasingly abrasive plant food. A good example is seen in the bank vole lineage *Clethrionomys* (= *Myodes*) in Eurasia, illustrated by Tesakov (1996).

Twelve samples from Eastern Europe and Western Siberia, arranged in chronological order independently of the character in question, show a substantial increase in hypsodonty of the molars across the past 2.5 Myr (Figure 2). The trend is largely unidirectional, but the most significant shifts in mean occur in the early part of the sequence, between 2.5 and 1.5 Ma, with virtual stasis thereafter – an example of varying evolutionary rate. Tesakov (1996) details other morphological changes that occurred through the lineage. The sequence has been codified as a series of chronospecies: *C. kretzoi* – *C. hintonianus* – *C. acrorhiza* – *C. glareolus* (the living species), but it is unclear whether this represents a series of cladogenetic speciation events or a single continuous lineage. There is considerable overlap in hypsodonty ranges between successive samples, consistent with a purely anagenetic mode, but further dated sampling and character analysis, across the species' range, would be required to test this.

Figure 2 Increase in crown height of lower M1 in the bank vole lineage (*Clethrionomys*) in Eastern Europe and Western Siberia. Redrawn from Tesakov A (1996) Evolution of bank voles (*Clethrionomys*, Arvicolinae) in the late Pliocene and early Pleistocene of eastern Europe. *Acta Zoologica Cracoviensis* 39: 541–547. The variable plotted, HH-index, is the square root of the sum of squares of two posterior dentine tract heights. Mean, range, and number of specimens shown for each sample.

Sagebrush Vole (*Lemmys curtatus*)

Most examples of mammalian evolution in the Quaternary, such as the bank vole example just described, are pieced together from dated samples from a series of different localities.

A long series of samples from a single stratigraphic sequence is rarer and particularly valuable because the relative age of the samples is not in doubt, and the location is constant, allowing clearer identification of trends driven by environmental change. The deposits in Porcupine Cave, Colorado, provide just such a sequence and have been studied by Barnosky and Bell (2003) and Barnosky (2004). The sagebrush vole (*Lemmys curtatus*) was traced through ten stratigraphic levels covering several climatic cycles between about 1.0 and 0.6 Ma (Barnosky and Bell, 2003) and compared to living populations of the species. The average number of discrete enamel loops in the molars increased through time (Figure 3), the mode shifting from four to six, the last 4-loop individuals known as recently as about 15–9 ka, so the morphological change accumulated across several glacial–interglacial cycles.

Water Voles (*Mimomys/Arvicola*)

An intensely studied lineage is that of *Mimomys* and its descendent, the living water vole *Arvicola*. A trend of increase in crown height is reflected by the height and form of the 'linea sinuosa' (the lateral enamel–dentine junction) and can be traced (Figure 4) although *M. davakosi*, *M. hassiacus*, *M. polonicus*, *M. pliocaenicus*, and '*M. ostramosensis*' (possibly synonymous with *M. pliocaenicus*) (Chaline and Laurin, 1986; Neraudeau et al., 1995; revised taxonomy given by Maul (1996) and personal communication). The ontogenetic basis for the crown height increase is a progressively delayed formation of roots (von Koenigswald and van Kolfschoten, 1996). As in the

Figure 3 Trend in average number of enamel loops (triangles) in first lower molar of *Lemmiscus* through the Porcupine Cave Pit Sequence, Colorado. Mean $\pm$ SE and sample size is shown from layer 9 (about 1 Ma) to layer 1 (about 0.6 Ma) and for modern *L. curtatus* from across its range (U.S. Great Basin and adjacent areas). Data from Barnosky and Bell (2003, personal communication). Numbers of triangles quantified as follows: 4 triangles = 4, 5 pinched = 4.33, 5 incipient = 4.67; 5 triangles = 5, 6 pinched = 5.33, 6 incipient = 5.67; 6 triangles = 6. Inset: left, the 4-triangle morphology; what would be the 5th triangle is widely confluent (arrow) with the anterior part of the tooth; right, the 5-triangle morphology; the enamel bands touch such that triangle 5 is separated from the front part of the tooth. Reproduced from Barnosky AD and Bell CJ (2003) Evolution, climate change and species boundaries: perspectives from tracing *Lemmiscus curtatus* populations through time and space. *Proceedings of the Royal Society of London Series B* 270: 2585–2590.

bank vole example, it is unclear whether this trend proceeded in a purely anagenetic mode or included speciation. In the replacement of *M. pliocaenicus/ostramosensis* by the next species in Europe, *M. savini*, it has been suggested that rather than a direct lineal transition, *M. savini* was an immigrant, having evolved from *Cromeromys* in Siberia (Neraudeau et al., 1995), although *Cromeromys* is rather poorly defined. In the final transition of the sequence, from *M. savini* to *Arvicola terrestris cantiana*, roots cease to form at all, so the tooth can grow continuously throughout life as it wears (Figure 4). In this respect, it differs from the *Clethrionomys* lineage, where hypsodonty increase ceased but roots continued to form.

The subsequent *A. terrestris* lineage demonstrates a further evolutionary trend, but in a different character (Figure 5). The sequence has been investigated by Heinrich (1987), van Kolfschoten (1992) and others, sampled across more than 20 horizons in northwest continental Europe between about 400 and 10 ka BP. The molars of these voles comprise a series of enamel loops, each loop formed of a concave 'leading' edge and a convex 'trailing' edge. There was a reduction in the thickness of the trailing edge until it became thinner than the leading edge, quantified by a ratio between the two (enamel quotient or SDQ) (Figure 5). A very similar trend is seen in samples from MIS 13, 11, 9, 7, and 5e from England (Parfitt, 1998, who also discusses other character changes in this lineage).

This approximately gradualistic trend of reduction in SDQ in central and northern European voles from MIS 11 to 6 was interrupted by the appearance of more 'primitive' (high-index) animals in the Eemian (MIS 5e), which then resumed the trend

Figure 4 Increase in crown height and change in the form of linea sinuosa in molars of the European *Mimomys-Arvicola* lineage. Modified from von Koenigswald W and van Kolfschoten T (1996) The *Mimomys-Arvicola* boundary and the enamel thickness quotient (SDQ) of *Arvicola* as stratigraphic markers in the middle Pleistocene. In: Turner C (ed.) *The Early middle Pleistocene in Europe*, pp. 211–226. Rotterdam: Balkema. Black, dentine; white, enamel; stippled, cement; linea sinuosa is the boundary between dentine and enamel. Roots are finally lost between *M. savini* and *A. terrestris*. The diagram also illustrates the theory that the lineage was interrupted by the extinction of *M. ostramosensis* and immigration of *M. savini*.

toward a reduced index until the late Weichselian (MIS 4–2; Figure 5). It is likely that the late Saalian (MIS 6) ice advance led to local extinction of *A. terrestris* in northwest Europe, followed in the Eemian by re-immigration of a more primitive form (van Kolfschoten, 1992). A similar pattern of evolutionary reversal is seen in voles from Central Europe (Hungary: Janossy, 1976), but the apparent inversion in southern France and northwestern Italy shown by Desclaux et al. (2000) was not confirmed by larger samples (Escudé et al., 2008), nor is the reversal seen in Eastern Europe (van Kolfschoten, personal communication). Röttger (1987) showed that even today there is a cline in SDQ of water voles across Europe, with those in the south and east showing a higher (more 'primitive') index than those in the north and west. If this pertained in the past, it would suggest repopulation of northern areas from the south or east in the Eemian.

The detection of a morphological reversal in this sequence is a reflection of its relatively high stratigraphic resolution. Such reversals quite likely occurred within longer, apparently unidirectional, sequences of other taxa, but are not perceived because of coarser sampling. In addition, this very rapid event was not a case of rapid evolution but of immigration. Many such apparently instantaneous morphological jumps seen in

Figure 5 Trend in enamel differentiation index (SDQ) of molars (lower M1 plotted) in the middle to late Pleistocene *Arvicola terrestris* lineage from Western Europe. SDQ is the ratio of enamel widths between the leading (l) and trailing (t) edges of each loop, averaged across each loop in the tooth. Stratigraphy from van Kolfschoten (1992, personal communication). Modified from von Koenigswald W, van Kolfschoten T (1996) The *Mimomys*-*Arvicola* boundary and the enamel thickness quotient (SDQ) of *Arvicola* as stratigraphic markers in the middle Pleistocene. In: Turner C (ed.) The Early middle Pleistocene in Europe, pp. 211–226. Rotterdam: Balkema.

the fossil record of a given region may be the result of migration events of already differentiated populations. The genuine evolutionary changes, which earlier produced that differentiation, could have occurred more slowly.

Escudé et al. (2008) showed a significant reduction in SDQ through the late Middle and late Pleistocene of France, with strongly overlapping ranges between successive samples, consistent with a purely anagenetic mode. A morphometric analysis of overall occlusal outline of the molar, however, failed to show any directional trend, emphasizing that a trend in one character may be accompanied by stasis or fluctuation in another.

Mammoths (*Mammuthus* spp.)

Arguably, the most detailed account of an evolutionary trend in a Quaternary large mammal lineage is provided by the Eurasian representatives of the mammoth genus, *Mammuthus*. A series of fossils from Europe spanning about 3 Myr demonstrates a broadly directional change in molar morphology, with an increase in the number of enamel 'lamellae,' thinning of the individual enamel bands, and heightening of the tooth crown, with concomitant changes in the skull. The transitions are

seen across four nominal chronospecies: *M. rumanus* (broadly late Pliocene), *M. meridionalis* (broadly early Pleistocene), *M. trogontherii* (broadly middle Pleistocene), and *M. primigenius* (broadly late Pleistocene). Viewed coarsely over the whole time-span, the sequence (Figure 6, open histograms) appears approximately 'gradualistic.' On closer examination, however, the pattern resolves into three intervals of stasis (no statistically significant change; colored vertical lines in Figure 6), corresponding broadly to the nominal species, with relatively rapid periods of transition in between.

When samples from other regions are added, a more complex picture emerges. *Mammuthus trogontherii*, appearing in western and central Europe around 800–700 ka, is found in NE China around 1.7 Ma (Wei et al., 2003; green star in Figure 6) and in NE Siberia around 1.2–1.0 Ma (Lister and Sher, 2001; black histogram in Figure 6). The transition from *M. meridionalis* to *M. trogontherii*, with substantial advancement of molar and skull morphology, therefore, appears to have taken place in the early Pleistocene of eastern Asia, probably in China, in response to a continental climate and partly steppic habitat (Wei et al., 2003; Lister et al., 2005). Only much later did it spread into Europe. This hypothesis of allopatric

Figure 6 Evolution of the Eurasian mammoth lineage. Modified from Lister AM and Sher AV (2001) The origin and evolution of the woolly mammoth. *Science* 294: 1094–1097. The graph shows the number of enamel plates (lamellae) in upper and lower M3; species identifications are also based on crown height (Lister and Sher, 2001, Figure 3B). Cross-hatch: *Mammuthus subplanifrons*, Africa; white: European samples, except gray, Voigtstedt; black, NE Siberia, plus Majuango, China (earliest *M. trogontherii*). Red: *M. meridionalis*; green, *M. trogontherii*; blue, *M. primigenius*. Dashed lines, Asian sites; solid lines, European sites. Site names linked by vertical lines are of approximately the same age. Site names separated by asterisks are significantly different in mean plate number.

speciation is corroborated by the finding, in Europe, of a period of overlap between indigenous *M. meridionalis* and apparently immigrant *M. trogontherii* in the interval 1.0–0.8 Ma, most notably at the Sinyaya Balka locality in SE Europe (Lister and Sher, 2001; Lister et al., 2005).

Further specialization to produce the woolly mammoth, *M. primigenius*, can be traced through a series of samples from NE Siberia, indicating that the genesis of this cold-adapted, grazing species took place in the Beringian region (Lister and Sher, 2001). The transitions from *M. trogontherii* to early *M. primigenius* in the interval 1.2–0.7 Ma (blue star in Figure 6), and thence to late *M. primigenius* by 0.4 Ma, each show an increase in grazing adaptation of the molars. Northern Siberia as the locus of origin of the woolly mammoth, presumably from semi-isolated populations of *M. trogontherii*, makes sense in terms of strong natural selection in this severe environmental regime (Sher et al., 2005). *M. primigenius* later dispersed into Europe and North America; its time of arrival is uncertain but is currently not definitively demonstrated until MIS 6 (about 180–140 ka).

In this way, the ‘broadly gradualistic’ mammoth sequence in Europe, formerly perceived as *in situ* evolution, can be resolved into a series of immigrations of successively more ‘advanced’ forms, those forms having originated, by cladogenesis, elsewhere. The processes of speciation and directional evolution (trends) are therefore intimately linked. The replacement of each species by its successor, not by anagenesis but by immigration and presumably competition, can even be viewed as a small-scale example of a trend driven by ‘species selection.’

It should be noted that even though the fossil record has pinpointed Early to middle Pleistocene China and northeast Siberia as likely areas of speciation, the duration of the cladogenetic events is known only within broad limits.

Microevolution

The above examples of directional trends (even with occasional reversals) must be viewed in the context of many other cases where there is little change through time (stasis) or, most commonly, fluctuation about a mean but with no net directional trend. The latter may in theory be seen in any character, but it is most commonly encountered in measures of body size or, at least, in the size of a measured dental or skeletal element (Lister, 1992; Blois and Hadly, 2009). van der Made (2010), for example, graphs changes in the size of a dental element in several large mammal species through the European Quaternary. Wolf (*Canis*) shows apparent directional change through the middle Pleistocene, with approximate stasis before and after, but both red deer (*C. elaphus*) and fallow deer (*Dama* spp.) show fluctuating patterns with little or no net trend. In a study of the marmot *Marmota* sp. at Porcupine Cave – from the same stratigraphic sequence demonstrating an evolutionary trend in sagebrush vole (see above) – no net change was seen in either nonmetric or metric traits (Barnosky et al., 2004). This emphasizes the individualistic nature of species responses.

Small-scale or reversible body size changes may often be ecophenotypic (a direct effect of the environment on development). In other cases, they may be genetically based (‘evolutionary’ in a strict sense), but these can be difficult to separate

paleontologically (Lister, 1997, 2004; Blois and Hadly, 2009). In terms of adaptation, size changes have often been regarded as responses to temperature increase, according to the theory that body size responds inversely to ambient temperature as an adaptation for heat regulation by altering the surface area to volume ratio (e.g., Davis, 1981). This model, inspired by ‘Bergmann’s rule’ of alleged increased size with latitude within modern species, has been widely applied to body size differences in Quaternary mammals. Kurtén (1968) found oscillation in body size of several mammalian species, large forms occurring in cold stages smaller ones in interglacials, and attributed the changes to ‘Bergmannian’ effects.

Others, however, have contested this interpretation, as body size is subject to many selective forces in addition to temperature regulation, and in the modern fauna, many species show trends contrary to Bergmann’s rule (McNab, 1971). An example is the American otter, *Lutra canadensis*, whose reduction in size toward the north is believed to be because holes in the ice become smaller in the arctic (Scholander, 1956). Such causal factors would be very difficult if not impossible to deduce in the fossil record. Several recent workers suggest that the duration and abundance of the plant growing season is the primary determinant of herbivore body size, which in turn selects for corresponding changes in carnivore size (McNab, 1971; Geist, 1987; Guthrie, 1990). Langvatn and Albon (1986), studying size clines in living red deer in Norway, attributed the larger size of animals toward the north to clines in the productivity and quality of plants. Under this interpretation, the Pleistocene tundra-steppe is regarded as a richer habitat for many large herbivores (and hence carnivores) than the interglacial forests (Geist, 1987; Guthrie, 1990), and the size reduction found by Davis (1981) at the Pleistocene/Holocene transition in the Middle East could have resulted from the vegetational response to increased aridity.

Such fluctuations must, in any event, be regarded as microevolutionary, in that they are short-term responses to local environmental conditions and do not lead to long-term trends, still less to speciation.

Biostratigraphic Value of Quaternary Mammal Evolution

Evolutionary trends are potentially of biostratigraphic value. In formal biostratigraphic zonation, they form the basis for the erection of ‘lineage zones,’ biostratigraphic zones based on a segment of the morphological trend in an evolving lineage (Hedberg, 1976). An ‘ideal’ evolutionary change from a biostratigraphic point of view would be one that is (a) easily observable (and preferably quantifiable) on the fossil remains, (b) genetically based, and (c) conforms to one of the following two patterns:

- a character that changes gradually, unidirectionally, and synchronously over the geographic range of the species;
- a new character that appears suddenly at a particular time, synchronously over the geographic range of the species.

However, studies of evolving lineages indicate that the rate of change is often very far from constant. There may be long periods of stasis, when little or no change occurs. At other times, gradual transitions may take place over considerable

timespans, but with a fluctuating rate of change. Finally, in certain circumstances, relatively very rapid changes may occur where the transition would be barely if at all resolvable in the geological record (Levinton, 1988). Two key consequences of this for biostratigraphy are as follows:

- (a) Morphological similarity between two samples, while consistent with their being the same age, does not guarantee it. They may be temporally separated by a period of evolutionary fluctuation or stasis. This is particularly likely when only a single character is considered. If many characters are examined, covering different aspects of the animal's anatomy, it becomes less likely that nothing at all will have changed over a significant period of time. Thus Rackham (1981) examined *Bison priscus* fossils from a series of British Devensian (Last Cold Stage) sites and found no significant differences between the samples on an array of biometric and morphological criteria. He therefore suggested that the samples were penecontemporaneous. Conversely, Lister et al. (2010) found significant differences in measurements of deer species across a series of early middle Pleistocene localities within a limited geographical area (southern England). They concluded that even if some of the samples date to the same interglacial stage, they could not be precisely contemporaneous.
- (b) The degree of morphological difference among a series of samples will be directly proportional to the time intervals between them only if the evolution was gradual and at a constant rate. In other cases, a sample of intermediate age between samples A and B may either still show morphology A (stasis) or already have arrived at morphology B (rapid change followed by stasis). The prediction of age based on morphology, assuming a constant rate of morphological change, is therefore not reliable unless there is clear independent evidence that this was the pattern of change. How frequently very rapid changes occur in practice is uncertain, and there must be an upper limit to the amount of change that can occur in a given period of time, which should become clearer as more independently calibrated cases are examined.

As well as lineage trends, the other major category of biostratigraphic data derived from species evolution is the first appearance datum (FAD) of a species in the fossil record, globally or in a given region. However, the distinction between these processes may be blurred in practice. Some of the 'first appearances' that are marked with a new species or even genus name are the result of a genuine speciation process in the sense of the splitting off of a new, reproductively isolated species from the parent (cladogenesis). In other cases, however, they may represent processes within a reproductively continuous lineage (anagenesis).

In either case, there is a further dichotomy: the apparent time of replacement of one form by another in a particular area may represent either the actual origination event of the new form, or else the time of its migration into that area, after origination elsewhere. The latter will be more common, unless there is sufficient geographical coverage to suggest that sampling is being done in the area of allopatric origin (as in the mammoth example, above).

The time of appearance of a species in a particular area may therefore have value as a local or regional biostratigraphic marker, but because of the potentially time-transgressive nature of its spread, FADs are a less secure basis for correlation the greater the geographic distance or the finer the time scale. Moreover, even in a single area, one cannot argue from a significant morphological difference between a species in horizon A, and its replacement in horizon B, that there must be a significant time interval between A and B. If the replacement was due to immigration rather than *in situ* evolution, it can have been effectively instantaneous.

In sum, mammalian evolution has potentially great value in Quaternary biostratigraphy, but because of the multiple potential modes of evolution, the pattern of change has to be established, for each lineage, in independently dated samples, preferably across the geographical range, before it can be confidently applied in biostratigraphy. It is, finally, important that morphological differences among samples be compared statistically, using adequate samples (Lister, 1992; Escudé et al., 2008).

Discussion

Rates of evolution observed in the Quaternary can be viewed in the context of both longer-term processes in the deep fossil record, and present and future observed or potential rates of adaptation. There is an apparent discrepancy between the extremely fast rates of observed historical transitions and laboratory experiments on the one hand, the generally slower Quaternary evolution on the other, and the even slower rates observed over longer geological timescales. Gingerich (1983, 1993) has gone some way to resolving this paradox by analyzing evolutionary rates measured over different timescales. He showed that fast rates are maintained for only a short time, and the longer the observed timespan, the lower the measured rate. Long evolutionary sequences will have included short episodes of change as fast as the modern examples, but over time these were averaged out with periods of slower change or stasis. This effect is enhanced by the reversals of trend, seen in Quaternary examples, which act as 'negative rate' and slow the net progress. Moreover, many of the fast transitions observed in short fossil or historical sequences are probably not evolutionary at all, but result from ecophenotypic or migrational effects.

In general, reviewing Quaternary mammal evolution, there is no clear evidence to support the idea that small mammals evolve faster than large ones (Liow et al., 2008). In terms of cladogenesis, it is clear that small mammals have produced greater numbers of species, for rather obvious demographic and ecological reasons. But in terms of rates of morphological change, there is no very clear difference between the dental sequences of the water vole and the mammoth, for example. This is perhaps unsurprising because neither of these lineages was evolving at anything near the maximal rate implied by laboratory selection experiments. Only closer to this limit might factors such as the faster generation time of small mammals have an effect. In the field, voles and mammoths took the order of 10^5 – 10^8 years to complete significant adaptive morphological changes, and the slowness of these net rates must

have been imposed by other factors such as environmental conditions, developmental constraints, and coadaptation of the animal's total phenotype.

It is not yet possible to confidently assess the relative contribution of gradualistic/anagenetic and punctuated/cladogenetic modes to evolutionary change. In part, this is due to biases in the fossil record or its perception. Biases in favor of 'seeing' punctuations include stratigraphic unconformities and mistaking rapid immigration for rapid origin. Biases in favor of 'seeing' gradualism include the greater ease with which an evolutionary lineage can be recognized the more gradational its links; and the selection for study of sequences showing clear directional trends (Gould and Eldredge, 1977).

The mammoth and water vole lineages, for example, were selected for detailed research because, as well as having a well-sampled sequence, each shows significant directional evolution. Moreover, the characters highlighted here (mammoth plate count and hypsodonty, and vole root formation and enamel differentiation) are those that show clear morphological trends. On the other hand, it would be wrong to ignore the many Quaternary mammalian taxa that 'appear' in the record without clear ancestry or a sequence of chronospecies behind them, such as the reindeer *Rangifer tarandus* (L). Whether this reflects punctuated equilibrium or simply one's ignorance (evolution – at an unknown rate – in an unsampled area) is not known. Also, in many cases, one cannot be sure whether a case of directional evolution, interpreted as an anagenetic trend, included complex patterns of population replacement or even directional sorting among the array of variously modified species (species selection). The mammoth example shows how complex a real process can be, incorporating elements of different evolutionary modes. It also shows that the perception of rate or of 'anagenetic/cladogenetic' mode is dependent on the time-scale over which it is viewed.

The examples quoted here cannot, therefore, yet be used to 'head count' the relative frequency of different modes or to assess whether Quaternary rates of evolution were faster than those of earlier periods (Lister, 2004). They do, nonetheless, provide valuable examples of evolution producing significant modification and demonstrating a variety of modes. The Quaternary is the unique interface where fruitful linkage can be forged between the deeper paleontological record, with its limits to resolution, and the neontological study of population genetics, with its limited time depth. The study of ancient DNA provides a further highly promising avenue of research in this respect (Ramakrishnan and Hadly, 2009).

Acknowledgments

The author is extremely grateful to Lutz Maul and Danielle Schreve for their valuable suggestions, to Thijs van Kolfschoten for discussion and permission to modify his water vole diagrams, and to Tony Barnosky and Chris Bell for discussion and very kind sharing of their data on Porcupine Cave sagebrush voles.

Dwarfing and Gigantism in Quaternary Vertebrates

Introduction

"I do not deny that there are many and grave difficulties in understanding how several of the inhabitants of the more remote islands, whether still retaining the same specific form or modified since their arrival, could have reached their present homes." (Charles Darwin, 1859: p. 396)

Islands have been regarded by scientists as a living laboratory of evolution, and a prime target for the study of forces influencing evolution and diversification. In response to the special characteristics of insular environments, plants and animals often undergo evolutionary changes which can be observed on islands of varying surface area. These include primary productivity and available resources, diversity, and intensity of ecological interactions, and time and magnitude of their isolation. Two main issues have been attentively scrutinized and debated: the loss of biodiversity of insular faunas and the peculiar changes undergone by island settlers, above all changes in body size shown by endemic reptiles, birds, and mammals. This pattern was first described in insular mammals by Foster (1964) as a tendency for rodents (and possibly marsupials) to increase and artiodactyls, carnivores, and possibly lagomorphs (rabbits and hares) to decrease in body size on islands, with insectivores supposedly showing no consistent trend. Afterward, this pattern was considered as a rule by Van Valen (1973), who postulated gigantism in smaller and dwarfism in larger species of insular mammals. Although the rule has a number of exceptions and departures from the predictions – which can be found among both extinct and extant endemic species of differing body size, trophic habits, and phylogenetic affinities – the 'island rule' continues to be a key topic and hotly debated issue in island biogeography.

Over time, a number of hypotheses have been formulated to explain causal mechanisms behind the graded body size change of insular vertebrates, and even recent overviews have presented conflicting points of view, confirming or rejecting the soundness of the 'rule.' Some authors maintain that it is a general principle (e.g., Benton et al., 2010; Köhler et al., 2008; Lomolino et al., 2006; Palombo, 2009; Welch, 2009 and references in those papers); others reject its generality, saying the 'rule' would be an artifact of comparing distantly related groups, showing clade-specific responses to insularity (Meiri et al., 2008). The role played by different factors in driving changes in body size has been interpreted differently by various authors, who mainly focused at times on the reduced (often absent) predation pressure exerted by large carnivores, host-island surface, limitation in trophic resources, population density and overcrowding, genetic segregation, and endogamy, and so on. Body size evolution of insular vertebrates, especially mammals, actually fluctuated in accordance with the synergistic influences of selective biotic and abiotic forces (geographic, climatic, and ecological characteristics of the islands,

biology of the focal species, structure of insular communities, species interaction, ecological displacement and release), whose relative importance and nature could vary on spatial and temporal scales, giving rise to a different body size evolution, even in species originating from the same ancestor.

Giants and Dwarfs: The Most Intriguing Case Histories

Miniaturized elephants and hippopotamuses, herbaceous plants becoming woody and as high as a tree, giant lizards, turtles and varans, insects and birds losing the power of flight, deer either as large as a dog or more than a moose, short-legged bovids with stereoscopic vision, little owls larger than horned owls, giant scavenger shrew-like insectivores larger than a cat, small rodents that had changed their size and life behavior: these are examples of extreme and fascinating animals whose ancestors are often difficult to know or imagine. During the Quaternary, dramatically specialized vertebrates inhabited a number of islands, from large to small, from close to significantly far from the mainland, scattered all over the world, from the Mediterranean sea to Indonesia, from the Eastern to Western Pacific Ocean, from the Caribbean to Canary islands. Their terrestrial ancestors reached these islands mainly by sweepstake dispersal, crossing either wide or narrow water barriers by swimming, rafting on floating vegetation, maybe drifting with the aid of currents, or else they crossed over on discontinuous terrestrial bridges or strips of emergent continental shelves. These mechanisms acted as a selective filter for dispersal.

Modes of colonization, pioneer species, and their evolution varied on each island as well on the same island over time. As a result, every insular fauna has its own unique structure. This depends on several interacting factors such as the type of islands (continental, oceanic, oceanic-like, either isolated or part of an archipelago), their size, physiography and climate regime, the distance separating the islands from the mainland, the nature of the barrier and its changing over time, the dispersal methods, the variety of ecological niches available on the islands, and the dispersal ability, ethology, and ecology of the nonflying mainland incoming species as well as the characteristics of the species already inhabiting the island (if any). These factors have been interwoven and subject to changes over time, sometimes leading to dramatic faunal turnovers.

Insular faunas, on the other hand, share some particular characteristics, above all the occurrence of 'dwarf' or 'giant' species in unbalanced, disharmonic, impoverished faunas, in which large carnivores, perissodactyls, and ungulates with little or no ability to swim, are rare or absent. This enables us to identify a number of 'fossil' islands, whose inhabitants constitute some of the most impressive examples of insular evolution. The preeminent cases of dwarfism among mammals (pygmy proboscideans) and gigantism (giant rodents and insectivores) are found in the fossil record. Accordingly,

paleontology offers unique insights into the long-term evolutionary processes and causal mechanisms that led to the peculiar insular ecosystems, shedding light, at the same time, on some intriguing paleogeographic issues.

Dwarf Giants: Proboscideans and Hippopotamuses

Proboscideans

Proboscideans were the most characteristic and common taxa in the Pleistocene disharmonic island faunas. Endemic stegodonts (*Sinomastodon*, *Stegoloxodon*, and *Stegodon*) were found in the Pleistocene deposits from Java, Sulawesi, Sumba, Timor, Flores, and Philippine islands. Dwarf *Mammuthus* species have been recorded in the late middle–late Pleistocene of Sardinia (*Mammuthus lamarmorai*), the early Pleistocene of Crete (*Mammuthus creticus*), and the late Pleistocene of Santa Rosa Island, California (*Mammuthus exilis*) (Figure 1). Endemic elephants that originated from southern European populations of straight-tusked *Palaeoloxodon* inhabited a number of Mediterranean islands (e.g., *Palaeoloxodon falconeri* and *Palaeoloxodon mnaidriensis* from Sicily and Malta; *Palaeoloxodon creutzburgi* from Crete, *Palaeoloxodon* spp. from Cyclades Islands, *Palaeoloxodon tiliensis* from Tilos, *Palaeoloxodon* sp. from Rhodos, *Palaeoloxodon cypriotes* and *Palaeoloxodon* sp. from Cyprus) (Figure 2) (see e.g., Agenbroad, 2012; Palombo, 2007, 2010; van der Bergh et al., 2001).

The frequency with which various proboscideans successfully colonized islands can be explained by their excellent swimming capacities, their trunk serving as a snorkel device, and their digestive system producing gasses which aid buoyancy. Moreover, these animals live and swim in herds; therefore, the founder group may have been sufficiently large to establish viable island populations. Sometimes proboscideans colonized a single island more than once, each time giving rise to endemic species differing in body size reduction, although the colonizers all originated from the same continental ancestor. They are therefore especially appropriate subjects for

evaluating causal mechanisms driving body size evolution in insular mammals. The species showing the most pronounced size reduction occurred in faunas where no other large herbivores were present (e.g., in the Sicilian ‘*Elephas falconeri* Faunal Complex [FC], the Cretan *Kritimys kiridus* FC, and in the *Stegodon sondaari* fauna from Flores). Conversely, species showing a less pronounced dwarfism occurred in impoverished, but quite diversified faunas either including large predators (e.g., the Sicilian ‘*Elephas mnaidriensis* FC and the San Teodoro Pianetti FC) or not including large predators (e.g., the Cretan *Mus minotaurus* FC). Proboscideans’ dwarfing was apparently unaffected by island surface area (Figure 3) and only indirectly influenced by the extent of island isolation from the mainland due to the temporal and geographical extent of barriers, acting as dispersal filters. Conversely it was strongly related to the presence/absence of other herbivores against which proboscideans must have competed for resources. When insular proboscideans were the only large mammals on an island, they underwent size reduction to an extreme degree, irrespective of the size of their mainland relatives, as shown for instance by *P. falconeri*, *M. creticus*, and *S. sondaari*, which can be regarded as the most prominent examples of the island rule.

The quite hypsodont (with high-crowned teeth) *S. sondaari*, a dwarfed species with a body weight of about 300 kg, is the only large mammal in the oldest Flores fauna, dated to about 900 ka. The fauna, strongly impoverished and disharmonic, includes the still-extant Komodo dragon, *Varanus komodoensis* (Figure 4), a giant *Geochelone* land tortoise, and a small crocodile. This fauna, disrupted by a volcanic eruption, was replaced at the transition from the early to middle Pleistocene by the *Stegodon florensis* fauna (van der Bergh et al., 2001). The dwarfed stegodon *S. sondaari* likely originated from Java elephants that reached Flores from the Sunda Shelf by crossing quite severe sea barriers.

M. creticus, likely a descendent of *Mammuthus meridionalis*, is known from a few remains, mainly molars, found at Cape Malekas (western Crete) together with the giant rodent

Figure 1 Artistic reconstruction of dwarf insular mammoths *Mammuthus creticus* (e), *Mammuthus lamarmorai* (d), and *Mammuthus exilis* (a) compared with their mainland ancestors *Mammuthus meridionalis* (c) and *Mammuthus columbi* (b). Drawing by S. Maugeri.

Drawing by S. Maugeri.

Figure 3 Body mass of endemic proboscideans plotted against the surface area of the islands they inhabited.

K. kiridus in deposits thought to be older than 800 ka. Its size has been estimated as slightly larger than that of *P. falconeri*. The latter is particularly known by the rich Sicilian material from Spinagallo cave (Syracuse, Southeastern Sicily), dated at about 500–450 ka (Figure 5). Its ancestor likely entered Sicily, and then colonized Malta, by the end of the early Pleistocene,

crossing a severe barrier, which prevented any other large mammal, except for the ancestor of the otter *Lutra trinacriae*, from reaching the insular system. As a result, the *E. falconeri* FC is disharmonic, poorly diversified and strongly endemic. Other than the elephant and otter, there were only small mammals that either evolved from endemic taxa that had existed since

Figure 4 Artistic reconstruction of the giant Komodo dragon, *Varanus komodoensis*. Drawing by S. Maugeri.

Figure 5 Mounted skeletons of the extinct (middle Pleistocene) *Palaeoloxodon falconeri* from Spinagallo Cave (early middle Pleistocene, Siracusa, Southeastern Sicily). This group (displayed at the Museum of Paleontology, Sapienza University, Rome, Italy) is said to include: (a) an adult female without tusks and with a height at the shoulder of about 80 cm; (b) an adult male high about 93 cm; (c) a young male, high about 35 cm; (d) a cub high about 24 cm. Courtesy of S. Conti, Director of the Museum.

the early Pleistocene Monte Pellegrino FC (*Leithia cartei* and *Leithia melitensis*, and *Maltamys* ex gr. *M. gollcheri-wiedincensis*, a distant relative of *Eliomys*) or from newly arrived species such as the ancestor of the endemic shrew *Crocidura esui*. This FC also included rather rich reptile and bird faunas, including giant strigiform birds (Figure 6). *P. falconeri* is the smallest endemic elephant found to date on the Mediterranean islands: the adult male would have a maximal withers height of about 110 cm and a body mass of about 170 kg, reduced by about 70% in height and 98.4% in weight with respect to its continental ancestor. The species shows precocious stunting of ontogenetic growth, as confirmed by skull features, tusk structure, and the proportions among the cranium, axial skeleton, and limbs. The peculiar shape of the nearly globose skull, similar to those of juvenile elephants, the extensive development of the brain case (the brain weight is about 1/60 of its body weight contra 1/1600 of the continental ancestor) (Figure 7), and some features of long bones indicate the persistence of juvenile traits in adult dwarf elephants (Palombo, 2010).

The smallest as well as medium-sized insular proboscideans – though evolved independently on each island and, therefore, taxonomically different – were characterized by

similar evolutionary traits such as the reduction of cranial bone pneumatization (the formation of air cells or cavities in bone), the decrease in the number of molar plates and the increase in enamel thickness, a relative increase in the brain size, less graviportal structure of limbs (columnar limbs with humerus and femur longer than radius-ulna and tibia-fibula, sometime adapted for slow movement because of large body mass), and a great morphological variability, at least in part associated, with an increased morphological and dimensional differentiation between sexes.

Hippopotamuses

Endemic hippopotamuses are known to be present in many different times and localities. They are found in late Pleistocene faunas of Madagascar. This included *Hippopotamus madagascariensis*, weighing about 400 kg, showing a typical aquatic habit, and *Hippopotamus lemerlei*, a more terrestrial and slightly smaller species weighing about 350 kg. They are also known from late middle to late Pleistocene faunas from Sicily, including *Hippopotamus pentlandi*, about 20% reduced in size with respect to its ancestor *Hippopotamus* ex gr. *H. amphibius*, and from Malta, where *Hippopotamus melitensis* was found. *H. melitensis* was smaller than the Sicilian species from which it likely originated. They are also known from the middle Pleistocene of Crete, where *Hippopotamus creutzburgi* is thought to have originated from *Hippopotamus* ex gr. *H. antiquus* and from the late Pleistocene and early Holocene of Cyprus, where *Phanourios minor* was found. The mainland ancestor and the actual time of dispersal of this species are uncertain (Figure 8).

Each population of dwarf hippo generally presents a wide range of morphological and dimensional variability, to the extent that extreme examples from the same island have sometimes been erroneously interpreted as two different species or subspecies (e.g., on specimens found on Malta and Crete). *Phanourios minor* (Figure 9) is undoubtedly the smallest (70 cm high at the shoulder) and the most specialized endemic hippopotamus, showing marked biometrical and morphological modifications of skull, dentition, and limb bones. Apomorphic characters (evolutionarily advanced character state), such as the lophodont dentition (teeth with cusps elongated to form narrow ridges), the quite stiff limb joints, the unguligrade structure (the animal walks only on its digits) of the autopodium (foot), indicate that the Cypriot hippo was mainly a browser, not a good runner, but able to negotiate rocky terrain (van der Geer et al., 2010). Similar limb modifications, shared by other hippos from the Mediterranean islands and more

Figure 6 Artistic reconstruction of the environment of Spinagallo Cave (southeastern Sicily, early middle Pleistocene) showing *Palaeoloxodon falconeri* and its accompanying fauna: the dormouse *Leithia melitensis*, the otter *Lutra trinacrae*, the tortoise *Geochelone* sp., the lizard *Lacerta siculomelitensis*, the swan *Cygnus falconeri* (although it is not recorded in this site), the crane *Grus* cf. *G. melitensis*, the owl *Athena trinacrae*. Drawing by S. Maugeri.

evident as size reduction increases, are likely related to a habit of insular hippopotamuses being more terrestrial than that of their mainland (aquatic) relatives.

Anagenetic and Radiative Evolution: The Mediterranean Deer

During the Pleistocene and early Holocene, endemic deer, descendant from a number of different mainland ancestors (Megacerini, *Muntiacus*, *Diceros*, *Capeolus*, *Cervus*, *Dama*, *Axis*, and *Elaphurus*) were a common component of a number of insular faunas all over the world, from Japan to the Philippines, from Jersey to a number of Mediterranean islands. The Mediterranean insular deer, found in Eastern Mediterranean (Crete, Kassos, Karpathos, Amorgos, and Tilos) and Western Mediterranean islands (Sardinia and Corsica, Capri, Pianosa, Sicily, and Malta), belong to different mainland ancestors, and authors remain divided about the phylogenetic relationships, taxonomy, time of dispersal, and evolutionary history of most of them. No species with an entirely comparable adaptation existed on more than one island, therefore it is difficult to identify a dominant factor in their evolution. Evolutionary processes, mainly depending on intra-guild competition and nature of available niches, led to changes in size and adaptive strategy for a more efficient exploitation of resources under the peculiar environmental conditions of each island ecosystem, but causal mechanisms interplayed differently in shaping the evolution of each insular species.

The endemic deer from Sardinia and Crete are of particular interest. Although they are generally regarded as stemming from closely related ancestors (i.e., the Megacerini tribe), they underwent different evolutionary processes, even on islands with similar surface area and physiography. For instance, the

Figure 7 Comparison between the brain case of *Palaeoloxodon antiquus* (Pian dell'Olmo, Central Italy) (above) and *Palaeoloxodon falconeri* (female from Spinagallo Cave, Southeastern Sicily) (below). Drawing by M.R. Palombo.

sympatric speciation and radiation process of Cretan deer led both to 'dwarfism' and 'gigantism,' whereas in Sardinia endemic deer underwent a progressive decrease in size.

The Pleistocene endemic deer from Sardinia belong to the '*Praemegaceros*' group, as supported by some skull, mandible, and teeth features (Figure 10). The forerunner (?*Praemegaceros verticornis*) probably entered Sardinia during the late early

Figure 8 Artistic reconstruction of the dwarf insular hipopotamuses *Hippopotamus pentlandi* (Sicily and Malta) (b), *Hippopotamus creutzburgi* (Crete) (c) and *Phanourios minor* (Cyprus) (d) compared with the extant *Hippopotamus amphibius* (a). Drawing by S. Maugeri.

Figure 9 Mounted skeleton of the Cypriot dwarf hippopotamus *Phanourios minor*. Height at the shoulder is about 50 cm. Museum of Geology and Paleontology, University of Athens, Greece. Courtesy of G. Lyras.

Pleistocene low sea level episode (marine isotope stage (MIS) ?24–22) and survived on the island until 7000 years ago. During its anagenetic evolution (gradual evolution of an ancestral species to a descendant species with no branching or splitting of the lineage), Sardinian ‘*Praemegaceros*’ underwent a progressive size reduction, from the largest *Praemegaceros sardus* to the smallest latest Pleistocene population of *Praemegaceros cazioti*, found in Corbeddu cave. Metapodials (elongated bones in the feet) became shorter, but the Sardinian megacerines acquired a more agile gait on both hard and uneven ground and increased their consumption of dry grass as compared to their possible ancestor (Palombo, 2005).

On Crete endemic deer of different sizes, feeding behavior and locomotion (Caloi and Palombo, 1995; de Vos, 1996) were recorded from the late Pleistocene *Mus catreus* and *Mus minotaurus* FCs. Their forerunners probably reached the island by swimming during the late middle Pleistocene glacio-eustatic low sea level stand. No direct competitors were present when these deer arrived on the island. Consequently, many habitats and empty niches were available. This fact allowed deer to undergo an adaptive radiation. Some decreased in size, as

Figure 10 *Praemegaceros cazioti* from Dragonara Cave (late Pleistocene, Alghero, Northwestern Sardinia): reconstructed skeleton (on the left, modified from Caloi L and Malatesta A (1974) Il cervo pleistocenico di Sardegna. *Memorie dell'Istituto Italiano di Paleontologia Umana* 2: 163–246), and skull in dorsal (a) and lateral view (b). expected by the island rule, but others become larger than their mainland ancestors. Cranial and limb morphology, dimension, and proportion allow us to recognize six size classes (Figure 11): *Candiacervus ropalophorus* had a height of about 40 cm at the shoulder; *Candiacervus* spp. II (three morphotypes) was about 50 cm at the shoulder (Figure 12); *Candiacervus cretensis* was about 65 cm at the shoulder; *Candiacervus rethymnensis* whose size was comparable to the mainland species *Cervus elaphus*; the larger *Candiacervus dorothenensis* (= *Candiacervus* sp. V) was high about 150 cm at the shoulder, and the giant *Candiacervus major* (= *Candiacervus* sp. VI) about

200 cm. The smallest Cretan deer *C. ropalophorus* shows a modified locomotory system (lowering of centre of gravity, greater stability, low-gear locomotion, and stiffer joints), but brain/body mass proportion provides evidence that this endemic deer underwent only minor changes in the relative size of brain after its geographic isolation.

Shortened and Long Metapodials: The Strange Case of Balearic and Sardinian Bovids

Fossil bovids are unusual components of Quaternary insular faunas, only recorded in some Asian islands and in the Western Mediterranean, where the most intriguing species, showing highly endemic features, inhabited the Eastern Balearic Islands and Sardinia.

On the Balearic Islands, the only large mammals recorded in highly impoverished, disharmonic faunas, belong to six chronospecies of the *Myotragus* phylogenetic lineage, which evolved in isolation for more than 5 Ma before becoming extinct somewhere between 3700 and 2040 years BC (Bover et al., 2010). Evolutionary patterns within *Myotragus* include body size reduction, reduction in number of incisors and premolars, and changes in skull and postcranial morphology (Figures 13 and 14). The most advanced species, *Myotragus balearicus*, the Balearic Islands Cave Goat, was no more than 50 cm tall at the shoulder; its eye sockets almost faced the front of the face, granting stereoscopic vision; there was only one perennial-growth incisor in its mandible and its feet bones were dramatically shortened. Indeed, Balearic bovids acquired a slow, powerful walking gait by reducing limb length in a predator-free environment. This was done through a

marked shortening of metapodials and phalanges (the bones of the hind and front feet, respectively). Some remarkable similarities can be traced between *Myotragus* and both Miocene archaic 'goats' *Aragoral* (late Vallesian, MN10) and *Norbertia* (Turolian–Ruscinian boundary, MN13/14), which had robust metapodials, weak upper premolar styles and reduced second lower premolar, and therefore, eligible as putative ancestors of the Balearic genus. Since no bovid remains are known from the middle Miocene of the Balearic Islands, the ancestor of *Myotragus* presumably reached Mallorca sometime during the Messinian Salinity Crisis (MSC) by a temporary and selective emerged path. During the MSC, started at 5.96 Ma, parts of the Mediterranean basin became dry land because of a large fall of about 1500–2500 in the Mediterranean water level due to the isolation from the Atlantic Ocean.

On Sardinia, an endemic bovid, '*Antilope* (?*Nemorhaedus*)' *melonii* (= *Nesogoral melonii*) was first described, at the beginning of the last century, from breccias deposits cropping out at Capo Figari (northeastern Sardinia) (Figure 15), a locality whose karstic fissures yielded a number of bovid remains, one of which dated at about 1.8 Ma. The richest sample of bovids of the so-called '*Nesogoral* group' comes from Monte Tuttavista (Orosei, western Sardinia) (morphotype A = *Nesogoral* sp. 1 aff. *N. melonii* and morphotype B = *Nesogoral* sp. 2) (Figure 15), from a few sites ranging in age from the late Pliocene (Mandriola, *Nesogoral* sp.) to early Pleistocene (Capo Mannu, *Nesogoral* sp.), and from an unknown locality in the Campidano area (*Nesogoral cenisae*) (Palombo, 2009).

For decades, a close phylogenetic relationship between *Nesogoral* and *Myotragus* has been widely accepted. Nonetheless, although *Nesogoral* and archaic *Myotragus* share some cranial features (Palombo et al., 2006), differences in their limb bones cast doubt on this hypothesis. In particular, the metapodials of *Nesogoral*, despite their morphological and dimensional variability (Figure 14), are elongated and more slender than in archaic continental caprines such as *Aragoral* and *Norbertia*. On the other hand, their morphology and proportion are close to some representatives of the *Protoryx*/*Pachytragus* group, known from the late Miocene of Tunisia, Turkey, and Greece (Rozzi, 2010). In contrast to *Myotragus*, the Sardinian bovids likely retained the characteristics of long leg bones and the ability to run, due to the presence of a top predator, the hyaena *Chasmaporthetes melei* (Figure 16). Neither hyaenids nor bovids can easily swim or float, so it is rational to suppose that their ancestors did not cross water to reach Sardinia, nor was these sweepstake dispersals but, more likely, they reached the island by a selective path sometime during the MSC. Possibly at the same time, Sardinia was colonized by the unknown ancestor of *Asoletragus gentryi*, the strange bovid with stout, straight, almost conical and strongly backwards slanting horn-cores, known from a single incomplete skull found at Monte Tuttavista (Figure 15).

Bovids of a relatively reduced size have also been recorded in late middle Pleistocene to late Pleistocene deposits of Sicily (*Bos primigenius siciliae* and *Bison priscus siciliae*) and have been claimed on Pianosa (*Bos primigenius bubaloides*) and Malta (*Bos* sp.). Outside the Mediterranean, endemic bovids have been reported from the early–middle Pleistocene of Java

and from the Pleistocene-Holocene of the Philippines (*Bubalus cebuensis*, with a body mass of 150–165 kg, and *Bubalus* sp.).

Uncommon Island Settlers: Carnivora and Primates Including Hominins

Carnivora

Although the absence/scarcity of predators on islands has been assumed by some authors as a causal mechanism underlying ‘dwarfism’ and ‘gigantism’ of insular mammals, extant and fossil terrestrial and semiaquatic Carnivora are known worldwide also from a number of oceanic and oceanic-like islands, inhabited by impoverished, disharmonic endemic faunas.

Large predators have been reported from a few impoverished but balanced insular faunas (e.g., the middle–late Pleistocene *Panthera tigris* from Java and Japan, *Panthera spelaea* and *Crocota crocuta* from Sicily), but the only fossil endemic top predator thus far known is the early Pleistocene Sardinian hunting hyaena *C. melei*, known from a single partial skull from Monte Tuttavista (**Figure 16**). It remains unknown whether the ancestor was *Chasmaporthetes lunensis*, which might have entered Sardinia at the beginning of the Quaternary, or a Miocene species, dispersing to the island together with bovids and suids during the MSC (Palombo, 2009). *C. melei* is supposed to have been slightly reduced in size, consistent with the small size of its prey (the small monkey *Macaca majori*, the dwarf pig *Sus sondaari*, **Figure 18**, and the goat-sized bovids), and the lack of competitive pressure exerted by the two small mustelids, *Pannonictis*, and *Mustela* aff. *M. putorius*, present at that time on Sardinia.

However, the reduction in size of fossil insular carnivores was not a rule. Among canids, for instance, Java *Megacyon merriami* retained roughly the size of its ancestor *Xenocyon lycaonoides*, while its descendent *Mececyon trinilensis* was dwarfed. A reduction in size and significant morphological apomorphies (derived or advanced character states) characterize the fossil ‘wild dog’ *Cynotherium*, known from the late Early to the latest Pleistocene (11.35 ka BP) of Sardinia and the middle to late Pleistocene of Corsica (**Figure 19**). Although the actual phylogenetic significance of the presence of both hypercarnivorous (dental) and hypocarnivorous (cranial) features is still a matter of debate, *Cynotherium* possibly originated from an advanced European *Xenocyon*. Once on the island and consistently with its specialized hunting on small prey, *Cynotherium*

progressively reduced its size from the about 17 kg of *Cynotherium* sp. found in deposits older than 400 ka at Grotta dei Fiori cave (Carbonia), to the about 12 kg of the ~11.350 ka old *Cynotherium sardous* from Corbeddu cave (Oliena). *C. sardous* was likely a stalking hunter of the ochotonid *Prolagus*, as suggested by the high lateral mobility of the head and flexibility of its fore limb joints, as well as by the enamel structure and microwear pattern of its teeth (Novelli and Palombo, 2007; van der Geer et al., 2010).

All in all, patterns of size change of terrestrial carnivores, albeit highly variable, mainly depended on the size of the most readily available prey, while a less clear pattern characterized

the semiaquatic species, such as otters, whose remains, though scarce, have been found in many disharmonic faunas from the Mediterranean islands. Seven otter species have been described, three from the late Pleistocene of Sardinia: *Sardolutra ichnusae*, *Algalolutra major*, and *Megalenhydrys barbaricina*, the only giant otter possibly descended from the Corsican species *Lutra castiglioni*. In addition, *Lutra euxema* have been found from Malta, *Lutra trinacrae* from Sicily, and *Lutrogale cretensis* from Crete. The morphological variations and different types of adaptation of the insular otters seem to emphasize the differential characteristics already present in their ancestors. *Lutrogale cretensis* (Figure 20), for instance, accentuated the terrestrial adaptation already present in *Lutrogale*, while *L. euxema*, *L. trinacrae*, and the Sardinian otters exhibited a definitely aquatic habit, although they were adapted to different environments and had a quite different feeding behaviour (Willemsen, 2006).

Primates

Few fossil Quaternary primates have been recorded from islands elsewhere. They include the well-known late Pleistocene–early Holocene strepsirrhine primates endemic to Madagascar, among which very large extinct fossil lemurs (*Hadropithecus*, *Archaeolemur*, and *Babakotia*) as well as giant species (*Megalapsis*, *Archaeoindris*, and *Palaeopropithecus*) have been recorded. Outside of Madagascar, we can mention the dwarf macaque *Macaca majori* reported from few early Pleistocene localities of Sardinia (Figure 18) and the Platyrrhine monkeys reported from Cuba (*Paralouatta marianae* and *Paralouatta varonai*), Hispaniola (*Anthillotrix bernensis*), and Jamaica (*Xenothrix mcgregori*).

On the other hand, insular primates include one of the most amazing and debated insular species: *Homo floresiensis*. Since its discovery, in a disharmonic, impoverished fauna including a dwarf proboscidean (*Stegodon florensis insularis*), endemic murids (among others *Papagomys armandvillei*, *Papagomys theodorverhoeveni*, *Spelaeomys florensis*), giant varans (*Varanus komodoensis* and *V. hooijeri*), and a giant marabou, *Leptoptilos robustus* (Figure 21), this so-called ‘hobbit’

Figure 18 Skulls of the Sardinian dwarf macaque *Macaca* aff. *M. majori* (a) and of a juvenile individual belonging to the pygmy pig *Sus sondaari* (b) from the early Pleistocene of Monte Tuttavista, quarry VI-3 (Orosei, Eastern Sardinia) (photograph by M.R. represents one of the most substantial and controversial paleo-anthropological discoveries of the last decade. The Flores endemic hominin, with its mixture of archaic and advanced features, large orbits, small cranial capacity (Figure 22), small body and short limbs, was alternatively regarded as phylogenetically related to a very archaic hominin stock, or as a small-brained dwarf species descendant from *Homo erectus*, or a pathologic, microcephalic modern *H. sapiens* (Aiello, 2010 and references therein). Recently published detailed descriptions of the skull and the rest of the skeleton, as well as data on the associated fauna and lithic implements, besides the environmental and geomorphological context, support the hypothesis that *H. floresiensis* was an insular dwarf species, although whether it was derived from a large-bodied *H. erectus* or from a different, smaller bodied early *Homo* spp., is still an unanswered question (Aiello, 2010; van der Geer et al., 2010).

A Glance at the Insular Small Mammals

Endemic Quaternary rodents are reported from all over the world (van der Geer et al., 2010). Murine murids (Old World rats and mice) were the most widespread, known from several Asian and Mediterranean islands, Madagascar, the Canary, Channel, and Solomon islands, while cricetine murids (New World mice and rats, voles, hamsters, and relatives) are described from the Galapagos and Antilles Islands. Glirids (dormice) and arviculids (voles, lemmings, and muskrats) were mainly present in the Mediterranean islands, ctenodactylids (African guinea pigs) only in the early Pleistocene of Sicily (*Pellegrinia panormensis*, Figure 23). Endemic hystricognath rodents were present during the late Pleistocene, if not earlier, on several small and large islands of the West Indies. Endemic lagomorphs (rabbits, hares, and pikas) were less common: during the Pleistocene ochotonids (pikas) were only present

Figure 22 Cast of the skull of *Homo floresiensis* from Liang Bua cave (late Pleistocene, Flores). Courtesy of J. De Vos, NCB Naturalis (Leiden, The Netherlands). Photograph by E. Kruidenier.

Figure 23 Incomplete skull in dorsal (a), lateral (b), and ventral (c) views of the Sicilian ctenodactylid *Pellegrinia panormensis* (early Pleistocene, Monte Pellegrino, Palermo).

on the Corso-Sardinian massif (*Prolagus figaro*, *Prolagus sardus*, **Figure 24**), Leporidae (rabbits and hares) are reported from the early Pleistocene of Sicily (*Hypolagus peregrinus*) and Sardinia (a new undescribed genus), the late Pleistocene of Ryukyu islands (*Pentalagus furnessi*), and perhaps Sumatra.

Insectivores are less common in Quaternary insular fossil assemblages. More-or-less distant relatives of the shrew *Asoriculus* are reported in Sicily (*Asoriculus burgioi*), Sardinia (*'Asoriculus' similis*, *'Asoriculus' sp. II*), Corsica (*'Asoriculus' corsicanus*) and the Balearic islands (*Nesiotites ponsi*, *Nesiotites hidalgo*). White-toothed shrews are known in Sicily and Malta (*Crocidura esui*, *Crocidura* aff. *Crocidura sicula*), Crete (*Crocidura zimmermanni*), the central Ryukyu Islands (*Crocidura orii*, *Crocidura watesi*), and possibly Flores. Finally, shrew-like insectivores have been recorded from the West Indies. Quaternary endemic moles seem to be restricted to Sardinia (*Talpa tyrrhenica*), solenodons have been restricted to Cuba (*Soledon arredondo*) and Hispaniola (*Solenodon marcanoi*), while a subfossil tenrec has been reported from Madagascar (*Microgale macphee*).

Consistent with the island rule's prediction, a number of fossil rodents significantly increased their size on islands, albeit a similar pattern can be found among some lagomorphs and insectivores. Among the largest rodents, the Sicilian *Leithia melitensis*, (**Figure 25**), in a predator-free environment, reached a size about double the size of recent dormouse, while giant rats from Flores (the still-extant *Papagomys armandvillei* at least twice the average size of *Rattus norvegicus*, and the slightly smaller extinct *P. theodorverhoeveni* weighed more than 1 kg) increased their size despite the presence of powerful predators such as *Homo floresiensis*, the Komodo dragon, and the giant marabou stork (*Leptoptilos robustus*) (**Figure 21**) (Meijer and Due, 2010). Although giant species have also been reported from the Galapagos (*Megaoryzomys curioi*) and the Lesser Antilles (*Megalomys audreyae*, *Amblyrhiza inundata*, **Figure 26**), this evolutionary pattern was not a 'rule,' and some rodents did not undergo significant size changes. On Crete, for instance, although during its anagenetic evolution (a pattern of evolution that results in a linear descent with no branching or splitting) the endemic Old World mouse (*Mus*) lineage underwent an increase in size from *Mus bataei* to *Mus minotaurus*, the latter was only slightly larger than the mainland *Mus* representatives.

Anagenetic evolutionary patterns are not uncommon among insular small mammals. However, such a pattern characterized three distinct Sardinian lineages: *Rhagapodemus/Rhagamys*, *Microtus (Tyrrhenicola)*, and *Prolagus sardus*. As a matter of fact, from the late Pliocene *Rhagapodemus azzarolii* to the most advanced late Pleistocene–Holocene *Rhagamys orthodon*, Sardinian mice show an increase in body size, increased hypsodonty, progressively advanced molar features, and the appearance of accessory tooth roots (Abbazzi et al., 2004). The large pika *Prolagus sardus* (Figure 24), present on the island from the late middle Pleistocene to Roman historical times, shows a clinal morphological variation of dental occlusal surface (the surface of the teeth that comes in contact with those of the opposite jaw during chewing) and an asymptotic increase in size (Angelone et al., 2008), despite the fact that it was the

preferred prey of *Cynotherium* in the Pleistocene and then became an important food source for humans from Upper Paleolithic to Neolithic times.

Giant Turtles, Dragons, and Crocodiles

It has generally been accepted that ecological release, accompanied by low predation and competition pressures in highly disharmonic assemblages, could provide an explanation for the gigantism of most of endemic reptiles on islands. Although the increase in size of insular reptiles is not actually a rule and their change of size, irrespective of the size of the mainland ancestors, depends on the interplay of several factors such as resource availability and, as regard to predators, the size of prey, it is undoubted that a number of impressive cases of gigantism can be found among fossil reptiles.

During the Quaternary period, islands have harbored several giant taxa, among which are lizards and tortoises. One of the most famous examples is the Komodo Dragon (*Varanus komodoensis*) (Figure 4), with a total length of over 3 m and a weight of over 150 kg. This species occurred on Australia during the early Pliocene to middle Pleistocene, on Flores from the early Pleistocene through the Holocene, and is still living on the Indonesian islands of Rinca, Flores, Gili Motang, Gili Dasami, and Komodo. Other fossil insular representatives of this genus have been described from Java (*Varanus* cf. *V. komodoensis* from the middle Pleistocene; *Varanus salvator* from the early Pleistocene) and Timor (a new unnamed species from the middle Pleistocene) (Hocknull et al., 2009). The feeding ecology of this versatile predator has been a subject of long-standing interest and considerable conjecture. The most recent studies suggest that the combination of highly and very specifically optimized cranial and dental architecture, together with a capacity to deliver a range of powerful toxins, minimizes prey contact time and allows *Varanus* to kill a wide range of prey including large taxa, such as the 40 kg Sunda Deer (Fry et al., 2009).

Many other lizards, iguanas, and geckos are good examples of insular gigantism. These include endemic species that are either extant or fossil, such as *Hoplodactylus* and *Oligosoma* (= *Cyclodina*) *northlandi* from New Zealand, *Gallotia* from the Canary Islands, *Aristelliger titan* from Jamaica, *Anolis roosevelti* from Culebra Island, Puerto Rico *Conolophus* from the Galapagos Islands, *Lacerta siculimelitensis* from Sicily and Malta, *Brachylophus* sp. from Lifuka (Tonga), and *Cyclura* from the West Indies.

Extant chelonians (tortoises and turtles) span almost four orders of magnitude of body size, including the famous insular giants *Geochelone gigantea* (from Aldabra in the Seychelles) and *Geochelone elephantopus* (from the Galapagos Islands). Although the evolutionary determinants of size diversity and gigantism in chelonians are still poorly understood, a pronounced relationship between habitat and optimal body size has recently been found in this group (Jaffe et al., 2011). In addition to the living forms, several insular giant tortoises have been reported from Pleistocene and Holocene fossil material from all over the world (e.g., Cuba, Madagascar, the Seychelles, Bahamas, Moro Island, Curaçao, Sicily, Malta, Mallorca, New Caledonia, Timor, Java, Sulawesi, Flores).

Figure 27 Mounted skeleton of the middle Pleistocene crocodile *Toyotamaphimeia machikanensis* from Japan. Moscow Paleontological Museum (Moscow, Russia). Photograph by D. Vasilyan.

Finally, we might mention among large insular crocodiles (more than 3 m long) the terrestrial *Mekosuchus inexpectatus* from the Holocene of New Caledonia, *Mekosuchus kalpokasi* from the Holocene of Vanuatu, *Volia athollandersoni* from the Pleistocene of Fiji islands and the fresh water *Toyotamaphimeia machikanensis* from the middle Pleistocene of Central Japan (Kobayashi et al., 2006) (Figure 27).

Wingless Birds and Giant Owls

The same forces promoting gigantism in reptiles have been invoked to explain the evolution of large size in birds, mainly through the evolution of flightlessness. This trend is not restricted to predatory birds, because herbivorous birds, in the absence of herbivorous mammals, may also develop gigantism. The most famous examples are the eleven species of moa (Dinornithiformes) of New Zealand (Figure 28), the larger representatives of which reached about 3.7 m in height and weighed about 230 kg (Bunce et al., 2003), the elephant birds (Aepyornithiformes) from the Quaternary of Madagascar and the dodo (*Raphus cucullatus*; Columbiformes) from Mauritius. Other giant and in some cases flightless pigeons have been reported from the Quaternary of Fiji (*Natunaornis gigoura*; *Ducula lakeba*), Rodriguez Island in the Indian Ocean (*Pezophaps solitaria*), Polynesia, Wallis Island in the southwest Pacific (*Ducula david*), New Caledonia (*Gallicolumba longitarsus* and *Caloenas canacorum*), Henderson Island in the Pitcairns (*Ducula harrisoni*) and many other islands.

Typically, the most dramatic increase in body size is shown by birds of prey (Accipitriformes) and owls (Strigiformes). The largest eagle known to have existed was the New Zealand endemic Haast's eagle, *Harpagornis moorei*, that reached 10–15 kg of weight and had a wingspan of 2–3 m (Bunce et al., 2005). Other Accipitriformes of increased size have been reported, including species from the Quaternary of the West Indies (Suárez and Olson, 2007). In addition, this region harbored a number of large-sized owls such as the titanic *Ornimegalonyx oteroi* (Cuba), *Bubo osvaldoi* (Cuba), and several species of *Tyto* (Puerto Rico, Cuba, Hispaniola, Barbuda, Antigua). During the Quaternary, other endemic representatives of this order occurred in

Figure 28 Sir Richard Owen standing next to the giant moa *Dinornis giganteus*. Modified from Owen R (1879) *Memoirs on the extinct wingless birds of New Zealand*. London: John van Voorst.

Sicily (*Tyto mouerchauvireae*, *Aegolius martaie*, *Athene trinacriae*) (Pavia, 2008), the Balearic Islands (*Tyto balearica*), Corsica and Sardinia (*Athene angelis*, *Tyto balearica cyrneichmusae*, *Bubo insularis*), Flores (*Tyto* sp.), Madeira (*Tyto* sp.), Hawaii (*Grallistrix*), Crete and Armathia near Greece (*Athene cretensis*).

Cases of gigantism can also be found in a number of different orders of birds such as Anseriformes (ducks, geese, and swans) (including *Cnemiornis* and *Cygnus sumnerensis* from New Zealand and *Cygnus falconeri* from Sicily), Gruiformes (coots, cranes, and rails) (such as *Aptornis* from New Zealand and *Grus cubensis* from Cuba), Galliformes (chickens, quail, ptarmigan, pheasants) (such as *Sylviornis neocaledoniae* from New Caledonia and *Megavitiornis altirostris* from Fiji), and Ciconiiformes (such as the flightless ibis, Threskiornithidae, of Jamaica and the giant marabou stork, *Leptoptilos*, of Flores and Java).

All in all, giant insular bird species are scattered over a highly variable set of islands, including continental shelf, volcanic, and continental plate islands. Although it is highly likely that their release from mammalian competition and predation has promoted gigantism associated with flightlessness in these forms, the extent to which this explanation works at all taxonomic levels is still debated (Meiri, 2007).

Glossary

Aurignacian: First Upper Paleolithic industry extending over much of Europe; dates range from ca. 39 000 to 28 000 BC. Characterized by blade technology and the development of a significant formal bone tool industry, it is named after the site of Aurignac (Haute Garonne, France).

Bone-Isotope Analysis: Analysis of stable isotopes such as ^2H , ^{13}C , and ^{15}N in bone from archaeological sites, in an attempt to determine the nature of the diet of the human or animal concerned.

Magdalenian: An Upper Paleolithic industry found in Western Europe. Named after the type-site of La Madeleine in the Dordogne département in France, it is characterized by blade industries, geometric microliths, and an elaborate bone tool technology, including harpoons, needles and spear points. Dated to between approximately 18 000 to

11 000 BP, the most frequently occurring large game species represented at sites are reindeer and horse, with ibex and red deer in upland areas.

Solutrean: An Upper Paleolithic industry found in France and Spain. Named after the type-site of Solutré in the Saône-et-Loire département in France it is characterised by finely flaked, symmetrical, unifacial and bifacial leaf points which reflect a high level of craftsmanship. Dated to between approximately 17 000 to 21 000 BP, the most frequently occurring large game species represented at sites are reindeer and horse.

Scavenging: Procurement of animal products (usually meat or bone marrow and grease) from carcasses of animals already dead, that is, not killed by the agent scavenging.

Taphonomy: The study of the processes through which organic material becomes fossilized.

Introduction

As recently as the 1970s, early humans were assumed to have been efficient hunters. They were regarded as hunter-gatherers concentrating largely on the taking of large game, spending little time on smaller animals and plants. The very idea of humans as scavengers, for example, let alone prey as opposed to predators, was almost anathema to the archaeological world. The situation has changed, however, as we now realize that the human–environment relationship is a complex and ever-changing one.

Interactions between ‘early humans’ (*Homo habilis* to *Homo sapiens*) and animals are today recognized as taking several forms, both economic and social/ideological. Within the economic realm, humans may be predator, prey, and competitors with the local carnivore population for faunal resources and shelter. Within a nonsubsistence framework, animals featured in belief systems. The occurrence of animal forms in both the rock and mobiliary art of later Paleolithic Europe, Asia, and Africa tells us that the relationship between hunter and prey was a complex one operating at an ideological as well as economic level.

Diet and Subsistence

Pre-Holocene human populations depended on wild resources, practicing a hunting, scavenging, fishing, and gathering lifestyle, interacting constantly with the faunal resource base around them. Bone-isotope analysis has firmly established that Neanderthals were top-level carnivores, consuming such a significant amount of meat in their diet (comparable or

even in excess of contemporary carnivores such as wolf) that it is extremely unlikely this was acquired through scavenging (Bocherens et al., 1991). In the majority of cases, Paleolithic hominins were ‘obligate’ hunters. Thus, their economic/dietary relationship with animals was a close one, which was usually unidirectional. Only the earliest hominins are regarded as having regularly been the prey or ‘the hunted’ (Brain, 1981) rather than the predator or ‘hunter,’ although later they were competing for resources, and it is here that we will start.

The Lower Paleolithic

During the Lower Paleolithic/early Stone Age (see 2.7 Myr–300 000 Years Ago in Africa, 1.9 Myr–300 000 Years Ago in Europe, 2.7 Myr–300 000 Years Ago in Asia), the picture reconstructed is often one of humans hunting only on a sporadic or opportunistic chance-encounter basis. Game was killed as and when encountered and little planning was involved. Hunting usually supplemented or was supplemented by frequent scavenging of large game. These ‘early humans’ of the Lower Paleolithic are frequently considered not to have been hunters but instead to have scavenged from carcasses left by other large carnivores (e.g., wolf, lion, and hyena) or those of animals which died ‘naturally.’ For example, at sites such as FLK Zinj in the Olduvai Gorge of Tanzania, Binford concluded that early humans scavenged rather than hunted (Binford, 1988). Instead of having access to complete carcasses, they picked over what was left behind by hyenas or leopards. Bunn and Kroll (1986), meanwhile, describe the same site as one to which hominids transported carcasses or bits of carcasses from elsewhere – irrespective of whether the latter had been obtained by hunting or scavenging. Once carcass segments had been brought to the

site, human activity was quite intense, for there is evidence of skinning and carcass dismemberment as well as bone marrow processing. According to [Blumenshine and Marean \(1993\)](#), however, the picture is more complex, being an amalgam of human scavenging and butchery, plus removal of selected body parts from the site by carnivores.

Similarly, [Echassoux \(2004\)](#), in her study of the fauna at the Lower Pleistocene site of Le Vallonet (Alpes-Maritimes, France), identifies evidence of human activity as minimal and sporadic; the site is one at which more evidence is seen of carnivore and rodent activity. This is clearly a site at which humans and carnivores each played a role in assemblage formation. However, the absence of butchery marks on carnivore remains (other than the bear, which may have been hibernating at the site) suggests that human and other carnivores did not 'interact' as predator and prey ([Echassoux, 2004](#), p. 48). Instead, both the hominids and carnivores took advantage of both scavenging and hunting opportunities which were presented to them. Meanwhile in the Levant, Ulbeidiya formation assemblages I-15LF/1-16 and II-23 are attributed by [Gaudzinski \(2004\)](#) to hunting rather than scavenging – illustrating the remarkable diversity in subsistence strategies available to very early humans.

Similarly, at Iserna-la-Pineta (Molise, South Italy), it has been suggested that the mixed faunal assemblage, with cervids, hippopotamus, rhinoceros, elephant, and bear, results from chance-encounter hunting supplemented by human scavenging of large game. The presence of marrow bone fractures and cut marks on long bones links the assemblage to human activity ([Anconetani, 1999](#)), while the fact that more than half the material is bison (*Bison schoetensacki*) has been attributed to early specialization. Fauna from Caune de l'Arago in southern France (Pyrénées-Orientales) is also diverse and dates to between 700 and 100 ka ([de Lumley et al., 2004](#)). The site has been identified as a long-term home base, a temporary seasonal site, a hunting stand, and a 'bivouac' or short-term shelter. Furthermore, hunting at the site during each of these occupation phases is slightly different. For example, [de Lumley et al. \(2004\)](#) ascribe specialist hunting to the short-term occupation phases of the site, while longer-term and seasonal occupations see a more generalized strategy. In Britain, the early middle Pleistocene site of Boxgrove (West Sussex), dated to ca. 500 ka, has yielded diverse evidence of exploitation of Etruscan rhinoceros, horse, and red deer ([Roberts and Parfitt, 1999](#)). The rhinoceros appears to have been dispatched on the edge of a lagoon at the site and then systematically butchered, with full access to the prime parts of the carcass, whereas the horse bears evidence of an impact mark in the scapula, assumed to be from a spear. Such spears are rarely preserved in the archaeological record but notable examples are known from Clacton-on-Sea in England ([Oakley et al., 1977](#)) and Schöningen in Germany ([Thieme, 1997](#)), both ca. 400 ka ([Roberts, 1999](#)).

Finally, it should also be remembered that the Lower Paleolithic is a time when hominids were frequently prey as well as predator. For example, at locality 1 Zhoukoudian (China), of the 42 nondental hominid skeletal elements, 28 (67%) show hyenid tooth marks – gnawing, biting, chewing, punctures, even regurgitation (see [Figure 1](#)) ([Boaz et al., 2004](#)). Despite the carnivore marks observed, no such marks are recorded on the rhinoceros bones at the site. Instead, these display cut marks ([Tong, 2000](#)), implying that here early

humans are both predator and prey – evidence of the complexity of early human–animal interactions.

The Middle Paleolithic

Moving from the Lower to Middle Paleolithic, the nature of the early human–animal relationship becomes more complex as the faunal record changes (see [Late Pleistocene of Africa](#)).

It has frequently been suggested that during the Middle Paleolithic, humans could not hunt large game – at least on a regular basis ([Binford, 1981, 1988](#)); instead, meat from species such as horse, bison, mammoth, and aurochs was obtained only by scavenging. At the Grotte Vaufray (Dordogne, France), where deposits date back to 300 ka BP, [Binford \(1988\)](#) sees at least three scenarios that explain the structure of the faunal record. Small or medium game found at the site results from carnivore rather than human activity. Large species such as horse result from scavenging by humans. Red deer, however, he attributes to a mixture of human and carnivore activity, the main carnivore being the dhole – a scavenger, sharing, with humans, access to game already killed by larger predators such as the wolf. Even an alternative viewpoint in which Neanderthals and dhole occupied the site sporadically at different times of year (Neanderthals in autumn, dhole in spring and summer) shows how complex, if perhaps less direct, the relationship remains ([Burgett, 1999](#)). The faunal material recovered at La Quina, however, results from both natural and human processes/activities. Accumulation of material by humans is indicated by marks resulting from butchery observed on the bones (see [Figure 2](#)). Subsequent damage and destruction by carnivores at the site point to scavenging of human kills by species such as hyena and wolf.

Chase invokes a picture of reindeer killed at or near the site, with carcasses prepared for transportation elsewhere and marrow consumed at the site ([Chase, 1999](#), p. 169). Occurrence of more adult than juvenile carcasses, abundance of medium adult or large carcasses, relative rarity of the 'less meaty' cranial/axial skeleton, and greater importance of cut marks on skull and distal long bones ([Chase et al., 1994](#), p. 298) can be attributed to hunting rather than scavenging at this Middle Paleolithic site. The scene in which the human forager is actively hunting is one which is repeated across much of Eurasia, most particularly at sites such as Salzgitter Lebenstedt (Germany) where systematic reindeer hunting is observed ([Gaudzinski and Roebroeks, 2000](#)).

When Curtis Marean looked in detail at the faunal assemblages associated with Neanderthals and early modern humans from Kober Cave (Zagros Mountains, Iran) and layer 10 at Die Kelders Cave I in South Africa, respectively, he found no reliable evidence for scavenging. Indeed, the patterns seen at both sites indicate hunting by the occupants of the sites in question ([Marean, 1998](#), pp. 132–133), followed, on occasion, by scavenging by carnivores – as indicated by carnivore tooth marks superimposed on cut marks at Die Kelders I (see [Figure 3](#)).

Mousterian humans in west-central Italy scavenged to a much greater degree than did their Upper Paleolithic counterparts, despite the fact that they were efficient hunters. [Stiner \(1994\)](#) sees a change in the importance of scavenging about 55 ka, before which many faunal assemblages, she

Figure 1 Carnivore (hyenid) damage on bones of *Homo erectus* from locality 1 Zhoukoudian. © Russell L. Ciochon, University of Iowa.

claims, resulted from scavenging. After this, hunting was the norm. Further west in southern France, this change is seen at least 15–20 ka earlier (Boyle, 1998), with scavenging only a secondary mode of subsistence during much of the Middle Paleolithic in Western Europe. Thus taphonomic study has shown us that although the difference between Middle and Upper Paleolithic hunters is small, they did not occupy the same resource niches.

The Upper Paleolithic

During the Upper Paleolithic (Eurasia), late Stone Age (Africa), and Paleoindian periods (America), an increasing degree of organization in, rather than complexity or type of, subsistence strategy is evident, especially during the second half of the period. Some equate this increased organization with a growing

degree of specialization, which Enloe (1999, p. 502) defines as ‘when a particular resource offers a better solution to the problems of year-round, long-term food acquisition than does a general mix of other potential food resources.’ This does not need to imply that only one resource was exploited – we are not, after all, talking about a form of monoculture, and other resources were surely also taken, if only to avoid the health problems, if not death, which result from dietary overspecialization. What it does suggest is that when it was necessary to choose between available resources, the advantages of exploiting just one or two probably outweighed those of taking others: the chosen resource(s) provided a yield greater than/or more appropriate to the needs of the hunter-gatherer at the time of selection. Hunter-gatherers are therefore rarely observed taking food in quantities which directly reflect natural abundance of food in the environment. Instead, obtaining food involves a number of

Figure 2 (a) Cut-marks on reindeer tibia from La Quina bed 8; (b) reindeer tibia shaft fragment used as a *retouche* – with two sets of marks. © P. Chase.

Figure 3 Photograph showing carnivore tooth marks superimposed on cut marks at Die Kelders I, indicative of initial human hunting and carcass processing followed by carnivore scavenging. Scale = 1 cm. © C. Marean.

factors, of which natural abundance is but one. Decision-making processes involve choosing between available resources, disregarding some, and perhaps concentrating on others for specific reasons at specific times. Choices depend not only on availability but also on variables such as:

1. labor costs (it may be necessary to disregard a herd of bison or even larger prey such as mammoth due to lack of manpower at the time of herd observation);
2. the type of yield sought (when seeking large skins, there is little point in hunting small or very small game such as rabbit and even less point in spending time at the riverbank catching salmon); and
3. the quality rather than quantity of game available.

Hence it is highly likely that hunters became expert at determining the condition of prey. In particular, procurement and use of fat from animal carcasses provide a way of coping with harsh conditions, especially at times of periodic hardship. Indeed, some species (e.g., reindeer and gazelle, typical resources of the period in Western Europe and the Middle East) are poorer in fat than others, so expanding the diet to include alternative

resources such as fish and birds increases fat intake and improves the overall quality of the diet. As every hunter-gatherer knows, fat meat tastes better, providing more energy than does lean meat, and so is more efficiently metabolized, storing both vitamins and essential acids (Fagan, 2004, p. 64).

At Upper Paleolithic sites in southwest France, this widening of the resource base is seen even when reindeer dominates faunal assemblages, in some cases almost to the exclusion of anything else. It becomes apparent because carcass processing of primary versus secondary species is clearly different. Secondary species are much more likely to be butchered intensively or very intensively – in order to increase carcass yield and dietary variety, especially when the species are rare or very rare. At Magdalenian sites such as La Madeleine, Limeuil, and Reignac, in the classic Vézère valley (Dordogne, France), reindeer dominates assemblages, and red deer and horse form distant seconds. However, the carcass-processing strategy adopted in exploiting these species appears to have been a much more intensive one than in the case of reindeer, with greater effort expended in order to procure greater yield (Boyle, 1990) when they were available. These resources ranked much higher in the Paleolithic diet in terms of desirability than did reindeer, and thus an element of ‘luxury’ featured in man–animal subsistence relationships. The hunter’s relationship with primary and secondary species is different. The predominant species, abundant either consistently or periodically in the local environment, forms the backbone of the economy but the relationship between humans and secondary species will probably be more intense.

Raw Material

Food is not the only thing which animals provide and which therefore features in man–animal interactions during the Paleolithic.

The existence of some fauna at sites may be attributed to their use as raw material, such as the mammoth bones and tusks at Milovice (Czech Republic), where two bone deposits have been interpreted as Gravettian dwellings probably using skins/pelts to form coverings (Svoboda et al., 1996; see Late Pleistocene Megafaunal Extinctions).

Skins and pelts were also used for clothing. Female figurines found, for example, at the Siberian site of Malta appear to be wearing hooded fur overalls (Poikalainen, 2001, p. 53; White, 2003). The presence of cut marks of the sort observed in Figure 4, in which we see marks close to the base of antlers from Combe Grenal (Dordogne, France), is indicative of skinning activity. The skins may have been used for shelter/roofing, clothing, or even containers for short-term storage and transport. One of the earliest-suggested European examples of the use of pelts in shelter construction is that of the Acheulian structure reconstructed at the Grotte du Lazaret and dating back some 400–500 ka (de Lumley, 1969), although it has also been suggested that the stone/bone configuration at the site results instead from natural taphonomic processes (see Villa 2004 and references therein), while trapping of Arctic fox, beaver, and other fur-bearing animals for pelts for the (multi)layered clothing is also possible.

Figure 4 Cut marks close to the base of antlers from Combe Grenal, possibly indicative of skinning activity. © P. Chase.

Bone and antler were also important raw materials throughout the Upper Paleolithic more so than during earlier periods despite their frequent use as soft hammers during knapping. Several bone tools are characteristic of the Aurignacian, including split-base bone points; eyed needles provide a tantalizing hint of stitched clothing during the Solutrean; Magdalenian Stages IV–VI are differentiated on the basis of barbed bone/antler harpoons, perhaps used for fishing. Analysis of material from the terminal Pleistocene (ca. 12.5–10.5 ka) at Niah Cave (Borneo) has shown that particular attention appears to have been paid to disarticulating Cercopithecidae (Old World monkeys) pelvic limbs (Figure 5) into upper and lower elements, a procedure which, although almost certainly reflecting preparation and consumption practices, may also reflect their use as raw material in bone tool production – a noted feature from this period at Niah. Analysis of the butchery further suggests that treatment of the bear cat (*Arctictis binturong*) at the site (see Figure 6) separates it from other species. This distinction points toward a hunter–prey interaction which is systematic to the point of taxonomic classification, so that procurement and carcasses-treatment processes distinguished it from other arboreal taxa at the site and even other civet cats. These studies, part of a forthcoming monograph on Niah Cave (Rabett and Piper, 2012), show that there are hitherto unseen components in early human–animal relationships of which we are only now beginning to catch a sight.

On a perhaps less functional level, bone flutes are also known – such as those from the Grotte d'Isturitz in the

Pyrenées Atlantiques of Southern France (White, 2003, p. 81) and from the Aurignacian level of Geissenklösterle (d'Errico et al., 2003, p. 41). Jewellery may also not have been essential in terms of subsistence and diet. Many of the personal ornaments of the Upper Paleolithic of Western Europe are made of animal material – bone, tooth, or ivory. The existence, in the Magdalenian burial at St.-Germain-la-Rivière (Gironde, France), (according to Vanhaeren and d'Errico), of numerous perforated red deer canines, a species almost completely absent from faunal assemblages in the surrounding region, suggests, according to Vanhaeren and d'Errico (2005), that they were prestige items of exotic origin resulting from long-distance trade. The presence of these, and of necklaces and pendants from sites such as Rocher de la Peine (Dordogne, France) (Figure 7) and Arcy-sur-Cure (Figure 8) emphasize an important aspect of the early human–animal relationship which may not only have been based on the tangible yield obtained, but may also have had a ideological or religious significance.

Ideology and Religion

As already suggested, the relationship between humans and secondary game species was frequently more intense and complex than that with the ever-available primary resources. This is particularly interesting when we consider that it is frequently these secondary species that form the bulk of the images of animals observed in Upper Paleolithic cave art. The main focus of the art is large and small ungulates and carnivores, with some portrayals of fish and birds; medium-sized ungulates (e.g., deer) are less frequently portrayed, despite comprising the larger portion of the faunal assemblages excavated.

In the three areas that form the main concentration of Paleolithic parietal and mobiliary art, Périgord-Quercy, French Pyrenees, and Franco-Cantabria, the relationship between faunal assemblage composition and artistic portrayal of animals does not, on initial inspection, appear to be a positive one.

At La Madeleine (Dordogne, France), for example, reindeer dominates the fauna but is secondary in the art; horse, on the other hand, dominates the art but is second in the fauna. At La Vache (Ariège, France), horse again dominates the art while ibex is the main faunal species, second in art. Meanwhile, the ibex, which dominates several Magdalenian faunal assemblages in Cantabria, is third in the art in the region (Straus, 1992). Altuna (1983) has also observed that at Cantabrian sites such as Ekain and Tito Bustillo, where horse and red deer dominate the art, faunal sample structure does not mirror artistic impressions. Instead, the importance of the large game species becomes apparent: Straus (1992, p. 180) views the larger bison (a species which is 4 times the size of red deer and frequently much more important in the art) as 'impressive beasts and sources of food bonanzas when procured,' while red deer was the main staple resource in the Altamira region – less spectacular but critical perhaps to day-to-day subsistence and survival. Following a similar argument, the greater size of horse over ibex may mean that the frequent rank reversal of these species, and horse over the reindeer, is more apparent than real.

But what does the art actually tell us about the nature of early human–animal relationships? Mithen has suggested that the purpose of Paleolithic art was one of information gathering,

Figure 5 Cut marks resulting from the disarticulation of a Cercopithecidae pelvic limb into upper and lower elements from Lobang Aangus, Niah Cave, Sarawak. © R. Rabett (Harrisson Archive, Sarawak Museum).

Figure 6 Cut marks on bones of bear cat (*Arctictis binturong*) from Lobang Aangus, Niah Cave, Sarawak. © R. Rabett (Harrisson Archive, Sarawak Museum).

Figure 7 A late Magdalenian necklace from the site of Rocher-de-la-Peine (Dordgoen, France), made of the teeth of bear, lion, fox and deer, and *Dentalium* shells (Photo, Randall White).

this information concerning the natural environment and available large game species in the local environment, more particularly the location and the condition of game (Mithen, 1990). He claims that the animals dominant in cave art (bovids and horse) were tracked individually, acting as backup species at times of economic hardship or at least when Cantabrian red deer or Périgord reindeer levels were low, perhaps seasonally. The way in which horse and bovids (in Cantabria at least) are portrayed provides, according to Mithen, information concerning methods of hunting the less frequently taken species – species which might have been taken so infrequently that even knowledge of hunting practices would not have been passed on readily from one generation to another. Thus, the pictures provide intergenerational information available at times of low game yield or economic stress. They are an indication of game species either available for exploitation when the painting was completed or possibly available in the future – an indication of potential resources.

According to González Sainz (1988), art ‘tracks’ hunting practices on both temporal and geographical axes. He relates the fall in frequencies of stags and hinds in mobiliary art, as well as an increase in ibex through the Magdalenian, to decreasing red deer hunting and the growing importance of ibex hunting as revealed by faunal assemblages.

Different hunting techniques are also portrayed. Kehoe (1990, 1999) has identified corrals, ‘extended corrals,’ and drive lines among scenes featured in Paleolithic cave art. For example, he identifies a horse drive on the south wall of the Axial Gallery at Lascaux (Dordogne) on the basis of a series of black dots leading to, and eventually touching, a rectangle, which he interprets as a corral and line of rocks around which horses are running. At the Grotte Villars, he sees a hunter facing a charging bison. At Trois Frères, in the Ariège, he has identified two images of bison drives (Kehoe, 1999, p. 253). At Altamira, meanwhile, based on the shape of the chamber itself, Kehoe considers the principal chamber to represent a corral. He considers the portrayal of both dead bison in the middle of the ‘painted ceiling’ and other bison facing outward, toward portrayed hunters, to be corroborative evidence (Kehoe, 1990). At the Turkish cave site of Öküzini, a limestone pebble, described by Marcel Otte and colleagues (Otte et al., 1995), is incised on both sides (see Figure 9), one of which bears an engraving which could indeed represent a corral and drive line. Such corrals and drives have frequently been observed and discussed in the ethnohistoric literature, most recently by Frison (2004), who, among several examples, describes a caribou ‘procurement complex,’ which included a line of stone cairns over a distance of 1 km which led the animals to a lake where they were killed.

Irrespective of anything else, the fact remains that the people who painted or engraved the images of Paleolithic art were hunters, or hunter-gatherers, dependent in a large measure on the wild game resources available in the surrounding environment (Straus, 1992, p. 187). The art reflects hunting practices, although the relationship between hunters and prey is often less direct than we might initially imagine, adding one more component to the complex set of interrelationships observed between early humans and the vertebrate faunas of the Paleolithic. Of course, whether these human hunters contributed greatly to the extinction of several Pleistocene faunal species, large and small, remains a hotly debated subject

Figure 8 Aurignacian pendant made from mammoth ivory from Arcy-sur-Cure (Photo, Randall White).

Figure 9 A limestone pebble from the Turkish cave site of Öküzini, incised on both sides. On one side there is a possible engraving of a corral and drive line. © M. Otte.

and is treated in more detail elsewhere (late Pleistocene Megafaunal Extinctions).

A Sign of Things to Come

Finally, recent analysis of dog mtDNA has suggested that the ancestral wolf was first domesticated (the first mammal to be so) as long ago as 15 ka BP in East Asia, with possible archaeological evidence known from Germany just 1 ka later and from Israel at 12 ka BP (Savolainen et al., 2002). It provides a

tantalizing hint of the ever-changing nature of the human-animal relationship of the final Pleistocene and offers a glimpse of the future as humans become steadily more dependent on a relatively small number of domestic animal resources. Of course, the degree to which all of the above can be said depends almost entirely on the archaeozoologist's ability to retrieve and understand useful data – such as the distribution of cut marks on bones – subjecting the data collected to a truly taphonomic approach, a methodology which has thus far raised as many questions as it has answered and will no doubt continue to do the same.

Acknowledgments

The author would like to thank the following people for help in locating and permission to use illustrations and for both online and more traditional modes of discussion of material: Phil Chase, Russell Ciochon, Randall White, Clive Gamble, Marcel Otte, and Ryan Rabett.

INDEX

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of four levels of heading. Location references refer to the volume number, in bold, followed by the page number. Page numbers suffixed by *f* indicate figures, *t* indicate tables, *b* indicate boxes, and *ge* indicate glossary entries. **Bold locators** refers to Articles.
